6.2.3 Effects of biodiversity on water distribution and quality in ecosystems

6.2.3.1 Introduction

Water is essential to all living organisms, and in turn the biosphere plays a crucial role in the transportation, transformation and redistribution of water on local and regional scales. In terrestrial ecosystems, vegetation plays the primary role in transferring water from the soil to the atmosphere; plants and animals also have significant effects on the movement of water into the soil. In terrestrial systems, living organisms often regulate the magnitude and rate of flow of water from one site to another; similar effects occur in some aquatic ecosystems. In both terrestrial and aquatic systems the biota can have measurable impacts on water quality (e.g. on composition of solutes, abundance and nature of particulates). Unfortunately there are few experimental studies exploring the links between biodiversity and water. Clearly, though, differences among organisms and communities in physiology, phenology and structure determine the type and magnitude of biotic effects. The text below summarizes some of the major influences of species and communities on water fluxes and water quality.

6.2.3.2 Distribution of water

In terrestrial ecosystems, precipitation landing in one place is either evaporated again into the atmosphere, absorbed or infiltrated into the soil, or transferred by surface flow as runoff to another spot on the landscape. At the landscape scale, the types, relative abundances, and relative spatial locations of ecosystem types affect the amount of water moving from one point to another. For example, diverse land-use and management practices in water catchments in South Africa have been shown to affect stream-flow behaviour differently by altering runoff surface and water storage capacity in different ways (Braune and Wessels

1981). Conversion of vegetation within a watershed from forest or shrubland to grassland is known to have both short- and long-term effects on stream flow out of the watershed, in both temperate and tropical systems (Knight *et al.* 1985; Heimsath 1993); these effects could be due both to differences in the balance between infiltration and run-off, and to differences in the water use of the different communities (see discussion of evapotranspiration, below). In stream ecosystems, the presence of tree species can influence the rate of water flow with consequent effects on hydrology, sedimentation and stream channel structure (Graf 1978; Blackburn *et al.* 1982). Similarly, the presence of coral reefs offshore, and of estuarine or coastal vegetation, moderates the energy of water and reduces erosive action along shorelines (Walsh 1967; Twilley 1988). Lagoons within 'closed' coral atolls experience different water circulation, nutrient dynamics and productivity than do waters adjacent to 'open' reefs (Birkeland 1987).

Biodiversity at the scale of functional groups or species also plays an important role in determining the distribution and rate of movement of water. In terrestrial systems, differences in canopy and stem architecture among plants result in differences in the amount of precipitation intercepted, the proportion of precipitation converted to stem-flow, and the proportion of precipitation that infiltrates the soil rather than running off. For example, in arid lands a vegetative cover of shrubs has a very different effect from one of grasses: a semi-arid grassland has relatively homogeneous, complete capture of precipitation leading to shallow infiltration, while a shrubland has bare areas with high runoff interspersed with other areas where stem-flow leads to deep percolation (Schlesinger *et al.* 1990). Among woody species in semi-arid systems, differences in, for example, stem angle and leaf display lead to differences in the impact energy of precipitation (throughfall), and in infiltration rates, etc. (Nulsen *et al.* 1986; Wood *et al.* 1987; Navar and Bryan 1990). The movement of water through lotic (flowing) systems may also be affected by species differences. Water flow in streams moving through coniferous forests is more frequently slowed by large logs in the stream bed, with resulting influences on water chemistry, temperature and invertebrate communities (Bilby and Likens 1980), because of the slow decomposition of conifer wood relative to that of deciduous hardwood (Molles 1982). Other organisms redistribute moisture in even more subtle ways: Keeley and Swift assert that oaks on coastal slopes in Mediterranean climates act to collect fog and dew, which significantly increases water availability at the site. Even single animal species can affect water distribution: for example, the presence or absence of beavers in northern forest ecosystems creates extremely different distributions of surface waters (Naiman *et al.* 1994).

6.2.3.3 Groundwater fluxes

The movement of water from the atmosphere and shallow soil layers to deeper portions of the soil profile is an important determinant of the structure and function of a terrestrial ecosystem, and also influences the 'loss' or leaching of nutrients from the surface layers of the soil. This flux to the groundwater, and removals from that groundwater which serve as sources of water elsewhere, is largely regulated at the functional group scale of plant diversity. Addition or removal of trees and phreatophytes (plants whose deep root systems reach the water table) has the capacity to alter the depth of the water table locally. For example, in Australia an introduced pathogen has killed trees and shrubs, reducing evapotranspiration and causing a rise in the water table (Shea *et al.* 1975). Deliberate removal of woody vegetation (to be replaced by seasonal agriculture) in Australia has resulted in a similar reduction of evapotranspiration, raising the water table, and salinization over large regions (McFarlane *et al.* 1993; Lyons *et al.* 1993). Reduced diversity of landscapes and of plant growth forms has reduced the systems' ability to absorb and buffer storms, so that peak flows after extreme precipitation events have increased (Nulsen *et al.* 1986; McFarlane *et al.* 1993). Species differences within a functional group can be significant: for example, the phreatophytic invader *Tamarix* has the ability to draw water from unsaturated alluvial soil, an ability missing in native phreatophytic trees of the southwestern USA (Busch *et al.* 1992). This difference affects the species' relative competitive abilities as well as their overall effect on soil and stream hydrology. Other examples of species' or functional group differences influencing flux to the groundwater come from the forestry and watershed management literature; for example, conversion of deciduous forest to conifers can reduce the flow of water to the groundwater (Schulze 1982), in part because interception of precipitation (and subsequent loss to evaporation) is greater (Swift *et al.* 1975). Hamilton and King (1983) reviewed the conflicting reports that changes in tropical forest cover did (or did not) alter groundwater percolation and streamflows.

Animal functional groups are important to groundwater fluxes as well: for example, the earthworms (which can be divided into different sub-groups by soil depth) are responsible for aeration and porosity in soils, which in turn affect the water storage capacity of the profile and the infiltration rates (Al Addan 1990; Joschko *et al.* 1992; Smettem 1992). Agricultural activities also have altered or reduced the soil macrofauna in many areas, changing the impacts of animals on the physical properties of soil profiles (including porosity; e.g. Abbott *et al.* 1979; Lobry de Bruyn 1990). In semi-arid and arid zones, where earthworms may be unimportant, termites and ants play a similar role (see Section 6.2.2). Plots of semi-desert where

ants and termites had been removed have demonstrated long-term decreases in infiltration and increases in runoff (Elkins *et al.* 1986; Whitford 1991).

6.2.3.4 Evapotranspiration

The transfer of water from the substrate to the atmosphere by vegetation is undoubtedly the single largest flux from biosphere to atmosphere (Schlesinger 1991). Carbon dioxide cannot be fixed into primary production without the loss of water molecules from the leaves of plants. At the functional group level, the phenology, root structure and physiology of plants have direct implications for the amount and timing of water transfer to the atmosphere via transpiration. For example, tilling and the resultant changes in *fynbos* vegetation (including a reduction of plant species diversity) resulted in greater moisture content in the soil during summer months (Davis 1992). Plant functional groups may influence water flux to the atmosphere even in aquatic systems. The presence of a surface aquatic macrophyte, the invasive water hyacinth, results in leafy cover over the lake surface, which decreases surface evaporation but greatly increases transpirational losses (due to the great surface area of mesophyll). The net balance between the two processes can alter water levels. In terrestrial systems, diversity of root morphology and depth (including the tendency of some species to form roots at or even above the soil surface) results in the extraction of soil moisture from different parts of the soil profile, and thus more complete exploitation of received precipitation (e.g., Patric 1961; Dodd *et al.* 1984; Knoop and Walker 1985; Sala *et al.* 1989; Golluscio and Sala 1993). Differences in the depth of rooting zones and thus of water use result in differences in the depth of carbonate deposition in arid land soils (Schlesinger *et al.* 1987). Diversity at the species level may also be important. Within a group of plants, individual species differ in their resistance to water loss, their efficiency of water uptake from the soil, and so on. Even genetic diversity can have measurable effects: in agricultural ecosystems, varietal differences in water use efficiency, stomatal resistance and the like are the focus of selection in some crop breeding programmes. Certainly at a landscape level, evaporation/transpiration from one ecosystem or patch can have an effect on microclimate (especially relative humidity) downwind. It has even been suggested that inputs of moisture by transpiration are significant enough to increase local probability of precipitation (Anthes 1984). Work in the Amazon Basin suggests that roughly half of local precipitation is derived from moisture transpired locally (the rest coming from oceanic air masses), and that forest vegetation also contributes by intercepting moisture that would not otherwise fall as precipitation; thus deforestation is expected to decrease local moisture availability considerably (Franken and Leopoldo 1984; Salati 1985).

Effects on the hydrological cycle may be indirect as well: climate models suggest that the effect of boreal forest in warming the soil (compared with bare soil or with tundra vegetation) regulates formation of permafrost, snow accumulation and persistence, and soil moisture (Bonan *et al.* 1992).

6.2.3.5 Filtration and assimilative capacity

Biological organisms also serve to alter water quality by performing various filtration, uptake or excretory processes, all of which affect the composition and concentration of various dissolved gases, solutes and particulates. Diversity at the landscape scale (that is, the types, relative abundances, and relative spatial locations of ecosystem types) affects the quality of water moving from one point to another. For example, the width of strips of native vegetation bordering a stream in an agricultural area will affect the sediment and nutrient loads in runoff reaching the stream (Peterjohn and Correll 1984), suggesting that the presence of belts of riparian vegetation in a largely agricultural landscape is important in limiting the eutrophying effects of agricultural runoff into freshwater ecosystems. Changes in landscape structure in dry tropical forest increase runoff, erosion and nutrient loss in runoff (Maass *et al.* 1988). Beaver activity determines the inundation of land in the Great Lakes region of North America, with consequent changes to nutrient cycling, sediment accretion, aeration and other properties of flowing water (Naiman *et al.* 1988). In shallow coastal marine areas, seagrass beds are known to serve as buffers, minimizing the sediment and nutrient loads that reach coral reefs from eutrophied waters (Ogden and Gladfelter 1983; Ogden 1988). Estuarine and floodplain vegetation is known to exert a strong influence on the chemical composition of water (e.g. Amazon River: Junk and Furch 1985; estuarine mangroves: Twilley 1988). At the level of functional groups and of species, a diversity of uptake mechanisms and metabolic pathways (in both plants and microbial assemblages) allows more complete and efficient processing of nutrients and pollutants. There is a burgeoning industry pursuing the use of wetland communities (both natural and 'constructed') for the treatment of water pollution (Tourbier and Pierson 1976). There is ample documentation of the effects of species-level differences on water quality in aquatic systems. For example, there were differences among tree species and among nutrients for the uptake of N and P from waste water 'processed' by cypress swamps in Florida (Ewel and Odum 1986), and the presence of floating macrophytes was an important additive effect. Introductions of non-native macrophytes can affect lake chemistry significantly (Lodge *et al.* 1988). Differences among species of mangroves result in differences in the decomposition of organic matter and thus shifts in the balance between particulate organic carbon and

dissolved organic carbon (Boto and Bunt 1981; Snedaker 1989). On a smaller scale, *Sphagnum* mosses are known for their ability to pump cations from surrounding water, thus regulating water pH and quality (Hutchinson 1975). Species effects may be significant in terrestrial systems too; where pollution has altered the abundance or the composition of trees, forested ecosystems have exhibited alterations of groundwater quality (Schulze *et al.* 1989; Last and Watling 1991).

6.2.3.6 Trophic cascades and other biotic influences on water quality

Consumption and trophic patterns of primary consumers and secondary consumers also represent the influences of biodiversity at the functional group/species level. In lakes without fishery exploitation, the fish assemblage will be dominated by large individuals; smaller, zooplanktivorous fish will be strongly regulated by predation. Then predation on zooplankton is light; these attain high densities and effectively regulate phytoplankton. With heavy fishery exploitation, though, the fish community becomes dominated by smaller individuals with varying levels of zooplanktivory. The net result is an increase in algal biomass, sometimes causing blooms and water quality problems (Carpenter *et al.* 1985; Carpenter and Kitchell 1993). A similar story involves the introduction of Nile Perch to Lake Victoria, resulting in the elimination of many native cichlid fishes, a disruption of local fishery patterns, an increase in algal blooms, and eventually increased erosion from surrounding landscapes due to altered patterns of fuelwood consumption for drying the larger fish (Ogutu-Ohwayo 1990; Witte *et al.* 1992). The composition of the fish community ultimately determines whether the system's productivity is limited by nitrogen or by phosphorus (Elser *et al.* 1988; Carpenter and Kitchell 1993).

Human activity (particularly nutrient enrichment) has apparently increased the incidence of toxic blooms of algae (e.g. red tides, flagellate outbreaks) in shallow seas. These species-level effects in turn have dramatic effects on water quality and on fisheries (higher trophic levels), as well as on the shellfish industry (Smayda 1990, 1992). Another example of a species-level impact is the invasion of zebra mussels into North American lakes and rivers, where the rapid population growth of this filter-feeding mollusc has affected food particle density and the abundance and diversity of native filter-feeding organisms (Nalepa and Schloesser 1992).

6.2.3.7 Summary and implications

Because of the great magnitude of the transpiration flux through vegetation, and because of the diversity of plant physiology and water use, changes in the diversity of vegetation at almost any scale can have dramatic effects on

the rate of movement of water from the soil into the atmosphere (with resulting impacts on soil and atmospheric water content). Diversity of the biota at the functional group level can also have significant impacts on the movement of water in the opposite direction, into the soil. And because water availability is such a basic constraint to primary productivity and other facets of ecosystem functioning, considerations of potential impacts should accompany any actions that could have the effect of altering vegetative cover or soil macro-organisms. In aquatic systems, organisms affect water quality more than distribution (although there are biotic influences on the hydrology and geomorphology of streams). In most cases a greater diversity of biological organisms leads to a higher water quality, as perceived by humans, and in this sense aquatic biota (from microbes to fish and macrophytes) perform valuable ecosystem services. While the appropriate comparisons have not yet been made, current understanding allows several predictions about the relative impact of biodiversity alterations on water distribution and quality in different ecosystem types:

- Effects of biodiversity changes on local water distribution are predicted to be greatest in arid and semi-arid systems, for several reasons: the low availability of water in general, the large effects of organisms in regulating infiltration and surface flow, and the relatively low diversity of functional groups and of species within functional groups. Similarly, the magnitude of biodiversity effects on water flow in aquatic systems will probably be in inverse proportion to the magnitude of water flow itself (i.e. greater in small streams than in large open-water seas).
- Biodiversity effects on groundwater flux (especially the presence or absence of phreatophytes in the vegetation) are predicted to be important in almost any terrestrial system where precipitation exceeds potential evapotranspiration and there is significant flow of water from the soil profile into the groundwater.
- Biodiversity effects on evapotranspiration at the landscape scale are probably more dependent on geography than on biome type. That is, the effects are predicted to be most significant where (1) climate allows the development of sufficient vegetation to maintain high rates of transpiration, and (2) regional geography results in local moisture supply being significant in relation to moisture transported by air masses from distant regions.
- An important question to be addressed is whether water quality is most affected by biodiversity where biomass (or some other index of the rate of biological

activity) is high relative to the volume of water. That is, one might argue that the chemistry of water in a large lake will be less sensitive to changes in biodiversity than in a small pond, or in the soil solution of a well-developed forest.

In summary, there is strong evidence that biological diversity at the level of functional groups has significant effects on major fluxes in the hydrological cycle (infiltration, percolation to the groundwater, evapotranspiration), with the magnitude of the flux usually being positively related to the number of functional groups represented. It is, however, premature to draw conclusions about the effects of different numbers of species within functional groups. Species-level differences in physiology can be more directly related to differences in their effects on water quality (which can be either positive or negative). We conclude that biological diversity plays a substantial role in the ecosystem services of water supply and filtration, so critical to human welfare.

6.2.4 Atmospheric feedbacks

6.2.4.1 Introduction

The biosphere interacts with the atmosphere in various ways with respect to biodiversity and ecosystem functioning. As a source of atmospheric constituents the biosphere contributes significantly to the chemical composition of the atmosphere and thus has a strong influence on important atmospheric properties and, hence, on climate. Vice versa, changes of climate will have a strong feedback on ecosystem functioning and biodiversity, and thereby will influence biogenic emissions. Biogenic emissions of atmospheric constituents may be entirely dependent on a few species or a single functional group of species. As a consequence, particular ecosystem functions constitute a high environmental risk: minor changes in species composition will produce a direct feedback on atmospheric properties, which will then affect other aspects of ecosystem functioning and biodiversity. The term ‘biodiversity risk’ is used here for this pattern of biosphere/atmosphere interaction. As the biosphere is also the most important sink for numerous atmospheric constituents, the flux of injurious compounds from the atmosphere to the biosphere can reduce biodiversity and impair essential ecosystem functioning, which may then feed back into the atmosphere. The following text summarizes the biosphere/atmosphere interactions that can affect biodiversity and ecosystem functioning and/or constitute a high biodiversity risk.

6.2.4.2 Biogenic emissions and atmospheric properties

The biosphere is the most important source of several atmospheric trace constituents, including dimethylsulphide (DMS), carbonylsulphide (COS), methane (CH₄) and nitrous oxide (N₂O), as well as non-methane hydrocarbons such as terpenes and isoprene (Table 6.2-1). DMS is the major biogenic sulphur compound emitted by planktonic algae in marine environments (Barnard *et al.* 1982; Bates *et al.* 1987). In the atmosphere DMS is rapidly oxidized by OH radicals to form sulphate aerosols (Graedel 1979; Niki *et al.* 1983) which are the most important source of cloud

condensation nuclei (CCN) in the marine atmosphere and thus have a strong influence on the type and abundance of clouds over the oceans (Charlson *et al.* 1987). Since the growth of planktonic algae is highly dependent on environmental conditions, DMS emissions from the open oceans are considered a regulatory factor of the climate that can feed back on biodiversity and ecosystem functioning. Although many marine algae contain and release significant amounts of DMS (Keller *et al.* 1989), high rates of production and emission are restricted to a few classes of marine phytoplankton (mainly Dinophyceae and Prymnesiophyceae). As a consequence, high DMS concentrations in marine water ('hot spots') are superimposed on relatively constant concentration levels of 1–3 nM and result from blooms of certain species, e.g. *Phaeocystis poucheti* (Bates *et al.* 1987; Berresheim *et al.* 1989; Saltzman and Cooper 1989). Therefore, DMS emissions and, hence, CCN formation over the open oceans constitute a high biodiversity risk. DMS is also emitted from terrestrial ecosystems (Rennenberg 1991); however, it will not have a significant impact on cloud formation over the continents because of the high CCN formation by the oxidation of sulphur dioxide (SO₂) emitted by fossil fuel burning (Schwartz 1988; Wigley 1989).

The relatively long-lived biogenic sulphur compound COS and its atmospheric precursor CS₂ (Jones *et al.* 1983;

Hynes and Wine, 1989) represent the major sources of sulphur in the stratosphere (Crutzen 1976; Lazrus and Gandrun 1977; Inn *et al.* 1979; Khalil and Rasmussen 1984; Hofman 1990). Oxidation of COS in the stratosphere results in the production of sulphate aerosols (Lazrus and Gandrun 1977), which influence the Earth's radiation budget by scattering sunlight back into space and interfere with stratospheric ozone (Hofman 1990). Therefore, biogenic emission of COS and CS₂ contributes to climate as well as to the intensity and spatial distribution of UV-B radiation reaching the Earth's surface (Charlson *et al.* 1987) which will feed back on biodiversity and ecosystem functioning. In marine environments, COS and CS₂ emission is dominated by coastal environments that are considered highly vulnerable to anthropogenic disturbance (Aneja *et al.* 1979). Emission of COS from terrestrial ecosystems seems to be restricted to bare soils. COS released from vegetated soils is rapidly taken up and metabolized by vegetation and thus does not reach the atmosphere (Rennenberg 1991). Recent requirements for sulphur fertilization in agroecosystems due to the prolonged use of low-sulphur fertilizers, and the increasing cultivation of high-sulphur crops such as rape, may be linked to increasing biogenic emissions of COS (Hofman 1990) which now constitute a significant biodiversity risk.

Next to CO₂, CH₄ is presently thought to be the most

Table 6.2-1: Biogenic emissions affecting atmospheric properties.¹

5. Papen and Rennenberg 1990; Bouwman *et al.* 1993; Papen *et al.* 1993;
6. Monson *et al.* 1991; Tingey *et al.* 1991.

important greenhouse gas (IPCC 1992) and is released into the atmosphere predominantly from biogenic sources (IPCC 1992). Biogenic CH_4 production is mediated by a single functional group of approximately 100 species of bacteria that require strictly anaerobic conditions (Heyer 1990). Therefore, biogenic CH_4 emission is restricted to anaerobic environments, i.e. natural and human-made wetlands such as rice paddy fields and the digestive tracts of ruminants and termites (IPCC 1992). Many other biomes may become transient sources of atmospheric CH_4 when temporarily flooded. The actual amount of methane emitted is not only dependent on CH_4 production, but also on CH_4 oxidation in aerobic zones of the corresponding environment: CH_4 oxidation by methylotrophic bacteria, a functional group of approximately 25 species (Green 1992), may consume as much as 80% of the CH_4 produced (Wassmann *et al.* 1993). In vegetated wetland soils, CH_4 is released into the atmosphere mainly via transport through the aerenchyma of the plants which may provide resistance to the CH_4 flux (Schutz *et al.* 1991). Thus, CH_4 emission from wetlands is determined by the balance of microbial populations and their interaction with vegetation. Because of the low number of species involved, this balance is highly vulnerable to disturbance at the ecosystem functioning and landscape diversity level.

Another important greenhouse gas is N_2O . It is accumulating in the atmosphere at an increasing rate (IPCC 1992) and may therefore become even more important in the future. Global N_2O production has almost doubled within the last 100 years by anthropogenic activities, and because of the long (150-year) residence time of N_2O in the atmosphere, the atmospheric N_2O concentration will only stabilize in about 250 years from now, even if N_2O production were to be maintained at the present level. As for CH_4 , a major part of the atmospheric N_2O is of biogenic origin (IPCC 1992): it is produced in aerobic soils by chemolithotrophic and heterotrophic nitrification and in anaerobic soils by denitrification (Papen and Rennenberg 1990; Bouwman *et al.* 1993), but may also originate from other processes so far not identified (Papen *et al.* 1993). As N_2O emission is dependent on the availability of substrates for these processes, biomes that are exposed to high loads of nitrogen by direct application of N-fertilizer (e.g. agroecosystems) or by its incidental input through the atmosphere via dry and wet deposition (e.g. temperate forests) are major sources of biogenic N_2O (IPCC 1992; Papen *et al.* 1993). In addition to interfering with ecosystem functioning and biodiversity by climate forcing, N_2O emission also constitutes a biodiversity risk, as chemolithotrophic nitrification is restricted to a small number of microbial species (Papen and Rennenberg 1990).

Volatile organic compounds, especially terpenes and isoprene, are produced and released into the atmosphere by

a large number of plant species (Monson *et al.* 1991; Tingey *et al.* 1991), especially by woody plants including Mediterranean shrubs, eucalypts and conifers which determine particular landscape patterns in several biomes (Table 6.2-1). This heterogeneous group of volatile compounds affects the chemical composition of the atmosphere by controlling the oxidation capacity of the troposphere (Chameides *et al.* 1988). Changes in the photo-oxidation capacity of the atmosphere will influence the abundance and the distribution of other radiative trace constituents such as ozone. Apparently, terpene emissions are dominated by *Pinus* species which constitute a functional group for the emission of these atmospheric trace gases (Tingey *et al.* 1991).

6.2.4.3 Fluxes of atmospheric constituents into the biosphere

The biosphere is not only a source, but also a sink of radiatively active trace gases and atmospheric pollutants. Depositions of atmospheric sulphur and nitrogen compounds of anthropogenic origin severely affect biodiversity and ecosystem functioning in temperate and boreal forests and grasslands, as well as in lakes and rivers, by acidifying of water and soils and unbalancing nitrogen and sulphur nutrition (Lauenroth and Preston 1984; Reuss and Johnson 1986; Schulze *et al.* 1989; Wellburn 1990; Pearson and Stewart 1993; Rennenberg and Polle 1994). In particular, the diversity and abundance of ectomycorrhizal fungi and lichens can be reduced in the presence of atmospheric sulphur and nitrogen compounds (Kozłowski 1985; McCool 1987). Air pollution by photochemical oxidants can cause severe species-specific damage in agroecosystems and horticulture (Guderian *et al.* 1985). Deposition of atmospheric pollutants also affects the diversity and functioning of microbial populations in the soil and, as a consequence, changes interactions between the soil and the atmosphere as feedback reactions. Acidification of forest soils eliminates chemolithotrophic nitrification, a significant source of atmospheric N_2O (Johnsrud 1978; Papen *et al.* 1993). Nitrogen input into forest soils reduces the oxidation of atmospheric methane and, thus, the sink strength of forest soils for this radiatively active trace gas (Keller *et al.* 1983; Steudler *et al.* 1989).

6.2.4.4 Climate change and biosphere/atmosphere interactions at the level of biodiversity and ecosystem functioning

The depletion of stratospheric ozone with the consequence of increasing UV-B radiation and the increase in radiatively active trace gases in the atmosphere with the consequence of global warming are considered to be the most important changes in climate presently occurring (German Bundestag 1989). Increasing UV-B radiation will have direct effects

on biosphere/atmosphere interactions at the level of biodiversity and ecosystem functioning. Impairment of photosynthesis, nitrogen metabolism and orientation of marine phytoplankton by enhanced UV-B radiation (Tevini 1994) may affect DMS emission into the marine atmosphere, and hence CCN formation, an important factor in the global climate. In particular, the generation of hot-spots of DMS emission connected with the blooming of a few classes of marine phytoplankton may be a sensitive process. Changes in marine phytoplankton will also affect marine food chains and thus the vertical flux of atmospheric CO₂ into the deep ocean layers (biogenic CO₂ pump). This will in turn have a severe impact on the atmospheric CO₂ concentration, and hence on climate. In terrestrial ecosystems, increasing UV-B radiation may affect not only biogenic emission from sensitive vegetation (Tevini 1994), but also the production and emission of radiatively active trace gases by nitrification in the upper soil (Hooper and Terry 1974; Endo *et al.* 1986). As biogenic emissions are temperature-dependent processes, global warming is expected generally to increase the biogenic production of atmospheric trace constituents, which will cause a significant negative feedback on global warming. Species-specific responses and interactions with ecosystem functioning have to be expected as a direct consequence of elevated atmospheric CO₂. Functional studies and model estimations indicate that changes in growth rates and biomass production due to elevated CO₂ levels are dependent on environmental factors such as nutrient supply and climate and differ between species (Jarvis 1989; Mooney *et al.* 1991; Woodward *et al.* 1991; Bazzaz and Fajer 1992; Gilford 1992; Bowes 1993; Korner 1993). These factors will also affect ecosystem functioning at increasing atmospheric CO₂ concentrations and, hence, the sink and source strength of the biosphere for atmospheric trace constituents.

6.2.4.5 Conclusions and management implications

The biosphere is an essential factor in determining the budget, abundance and distribution of the most important environmentally relevant trace gases in the atmosphere. As these atmospheric constituents play a central role in global climate, changes in the source or sink strength of the biosphere will strongly affect biodiversity and ecosystem functioning. In addition, the emission of atmospheric trace gases by, and their deposition in, the biosphere is itself an important ecosystem function, highly dependent on biodiversity. The prevention of changes in ecosystem functioning and biodiversity that will affect the composition of the atmosphere is likely to be one of the most important environmental policy issues of the immediate future. To support policy decisions in this direction, intensive research is required on biosphere/atmosphere exchange processes and their

interaction with ecosystem functioning and biodiversity. Studies on soil microbial/atmosphere interactions may be of particular significance in this respect.

6.2.5 The influence of biodiversity on landscape structure

6.2.5.1 Introduction

Here, we explore how changes in biodiversity can affect landscapes and the way they function. A landscape can be defined scientifically as a heterogeneous area made up of a cluster of interacting ecosystems that is repeated in similar form throughout (Forman and Godron 1986). Although we usually think of landscapes as covering tens to hundreds of square kilometres, they can be of any size and can be defined hierarchically. At one scale we might recognize a riverine landscape consisting of clumps of trees, grassy patches, bank habitats, reed beds and so on. From a broader perspective this landscape is subsumed as a riverine landscape element in a larger landscape consisting of rivers, valleys, ridges and so on. From the perspective of an aquatic insect, the bank habitat is a landscape in itself, made up of small communities of different terrestrial and aquatic plants, bare patches and so on.

Landscape structure consists of the spatial layout of the different landscape elements and the linkages between them. The way a landscape functions is determined by the interactions between the spatial elements, the most important of these being mediated by flows of materials, energy and organisms. Landscape structure is primarily determined by the geomorphological and edaphic features of an area, but is also modified by the complex of interactions between the elements of the landscape itself. Changes in biological diversity that affect the exchange of material, energy or organisms between the elements have the potential to disrupt existing landscape structure and functioning.

The many different species found in a landscape are, of course, essential components of that landscape. Thus, any change in biodiversity affecting a large number of species is likely to affect landscape structure and functioning. The conversion of forests or grasslands to agriculture are examples of such changes in biodiversity. These types of land cover changes are well documented along with the

changes in ecosystem functioning (e.g. Waring and Schlesinger 1985). They usually involve major human activity to bring about the initial change and sometimes also to maintain the modified landscape. They will not be discussed further in this essay, but instead we will concentrate on the less deliberate anthropogenic modification of biodiversity, and on cases where changes in biodiversity in one element of the landscape lead to changes in other elements.

In assessing the impact on landscapes of changes in biodiversity it is important to keep in mind the chain of causality that we are discussing. This is shown in Figure 6.2-2a where some event, action or impact leads to a change in biodiversity and this subsequently causes changes in the landscape. However, it is often difficult to distinguish this chain from that in Figure 6.2-2b where the impact affects both biodiversity and landscape but with no strong causal connection between biodiversity and landscape in either direction, or from Figure 6.2-2c where the chain of causality is reversed. Further combinations of chains of causality can be described but these are the main three. In this summary we have sought examples that

Figure 6.2-2: Chains of causality in assessing the impact of changes in biodiversity.

appear to be best described by Figure 6.2-2a but accept that in some cases other interpretations may be valid.

6.2.5.2 Specific systems

6.2.5.2.1 Arid systems. In arid ecosystems the redistribution and concentration of water, nutrients and sediments are important at several scales in achieving adequate growing conditions for plants. For example, in arid shrublands, each individual shrub is a 'fertile island' where nutrients and water are concentrated (Garcia-Moya and McKell 1970; Noy Meir 1985; Garner and Steinberger 1989; Friedel *et al.* 1990). Introduced herbivores, or changes in the concentration of domestic and native herbivores, around new watering points for example, can disrupt these fertile islands and lead to changes in biodiversity and eventually the structure of the surrounding landscape. Introduced species that occupy the transfer areas, such as shrubs and trees invading watercourses, can disrupt the concentration process and lead to the loss of other species.

The stripe process, which is found in many arid regions of the world (White 1971), is an example of the resource concentration process at a larger scale. In these systems vegetation is clumped in parallel, narrow bands and the soil between the bands of vegetation is usually almost bare. In heavy rainfalls water quickly runs off bare areas but is trapped in vegetated areas. These systems occur in landscapes with slopes of less than 0.6° and relatively impervious soil surfaces. Measurements have shown that the stripe process can effectively double the amount of water received in the stripes and the development pattern in stripes is species-dependent (Montaña *et al.* 1990). The pattern of stripes can develop initially either from the loss of surrounding vegetation in previously vegetated areas or from the spread of vegetation around an initial colonizer in previously bare areas (White 1971). The system can be disrupted by changed herbivory patterns that break the runoff surfaces (e.g. sheep tracks; Tongway and Ludwig 1990), by introduced species colonizing the runoff surfaces, or by grazing in the stripe vegetation.

At a larger scale the resource concentration process has been described as an 'erosion cell' (Pickup 1985). Arid lands are often a mosaic of erosion cells each consisting of erosional, transfer and sink areas. Changes in grazing patterns brought about by human activity can increase the susceptibility of land surfaces to erosion (e.g. by removing plant cover or by breaking up soil crusts), so initiating new erosional cells and thus altering landscape patterns.

6.2.5.2.2 Temperate and boreal forests and grasslands. In more mesic systems the concentration process described for arid systems is not as important. Instead, the main effect of changes in biodiversity is through the disruption of disturbance regimes leading to changes in the landscape patterns that result from disturbance.

Common examples involve fire. Any gain or loss of species that contributes to heavy fuel loads is likely to affect fire regimes and these changes in disturbance regime can lead to significant changes in landscapes. An example is the impact of introduced herbivores (sheep) to native pastures in temperate to semi-arid areas of eastern Australia. Increased grazing pressure has reduced the grass biomass (and possibly diversity) and, coupled with fire suppression activities by landowners, fire frequencies have been reduced. This has led to dramatic increases in the density of many shrubby species previously kept in check by fires, and the conversion of large areas from a mosaic of grass and shrublands to shrub thickets (Griffin and Friedel 1984).

Beavers (*Castor canadensis*) provide an example of the loss of a single species leading to major changes in landscapes (Hammerson 1994; Naiman *et al.* 1994). It has been estimated that in parts of North America the density of beavers was 0.8/km along streams of all sizes (Jenkins and Busher 1979) and that they were the major element in creating patches of 0.5 to 24 ha in forested landscapes (Remillard *et al.* 1987). They do so by creating ponds, affecting stream flow, opening the forest canopy, changing nutrient distribution and creating habitats favourable to some species (e.g. willows, waterfowl) and unfavourable to others (e.g. aspen, cottonwood, running-water invertebrates). Their loss leads to a reduction in landscape heterogeneity, although their influence on the landscape may persist for centuries. For example, beavers disappeared from England about 1000 years ago but their influence can still be traced in the distribution of fens and peat areas (Darby 1956).

Moose (*Alces alces*) and Alaskan snowshoe hares (*Lepus americanus*) also play a keystone role in the composition and structure of boreal forests, and their presence or absence can affect the distribution and abundance of many other species (see 6.1.6).

6.2.5.2.3 Tropical savannahs. The complex interactions leading to the unstable balance of trees and grasses in savannah systems have been summarized by Walker (1987). In the alternating wet and dry tropical systems, changes in biodiversity can affect landscape functioning both by changing nutrient concentrating processes and by changing the fire regime as described above. Also, the loss of a few species can lead to a significant flow-on of effects that results in changes in landscape structure. An example is the role of termite mounds in acting as sites for the establishment of tree clumps (Menaut and Cesar 1982). Abandoned termitaria provide higher nutrient concentrations, greater water availability and local protection from fire, and thus favour the establishment of tree seedlings over those of grasses. The number of such mounds can be reduced by domestic

stock, so reducing tree regeneration and changing the nature of the savannah landscape towards a grassland.

Large native herbivores, such as elephants (*Loxodonta africana*) and hippopotamuses (*Hippopotamus amphibius*) affect savannah structure directly (Cumming 1982). Elephants physically remove trees and both species create paths that can eventually lead to new erosional cycles. Hippopotamus trails have a major influence in drainage patterns and thus on wetland landscapes (Laws 1981). The loss of these large species and their replacement by smaller or domestic herbivores usually leads to an homogenization of the savannah landscape.

6.2.5.2.4 Wet tropics. In wet tropical systems it appears that landscape patterns are less affected by changes in biodiversity *per se*, and that the biological diversity of most functional groups is so high that the loss of one or a few species has little effect (Janzen 1981). Landscape pattern is a consequence of topography and small-scale events such as blow-downs. Human activity, such as shifting agriculture and land clearance, can have major effects on biodiversity and landscape patterns. Changes in landscape patterns (e.g. edge exposure and fragmentation) may have continuing effects such as edge die-back and blow-down (Lovejoy *et al.* 1984), but the changes in landscape patterns appear to be the direct consequences of the human actions and are not moderated by changes in biodiversity directly (i.e. the chain of causality is most likely as in Figure 6.2-2b or c).

There are examples of key species affecting rain forest patches in wet-dry tropical regions. In Australia water buffalo, a recent introduction from Asia, seek out small rain forest patches where they create large wallows that are invaded by grasses and herbaceous species, many of which are also introduced. The wallows are more susceptible to fire than the rain forest itself and carry the frequent fires from the surrounding drier woodlands into the rain forest patch (Russell-Smith and Dunlop 1987). This is leading to the loss of rain forest patches within the landscape.

6.2.5.2.5 Aquatic systems. Water is a dense and mobile medium which readily carries material, energy and organisms between components of aquatic 'landscapes' (here interpreted as the solid substrate beneath the water rather than structures in the water column itself). Water is the dominant linkage between elements of the landscape, and organisms are most likely to affect landscapes by acting as filters or barriers to the transport process. In coral reefs the diverse biota literally create the landscape where the existence of atolls and barrier structures is dependent on the diversity of coral and planktonic organisms responsible for substrate formation and for the continued nutrition of the living landscape (see 6.1.10).

The destruction of mangrove forests can lead to a loss of the filtering process that traps soil sediments in the surface flow from the landward side (Ogden 1988). Seagrass beds

perform a similar role in shallow coastal areas (Ogden and Gladfelter 1983). The loss of these species may allow large pulses of nutrients and sediment to be deposited on nearshore marine systems leading to major impacts on reef structure and diversity (D'Elia 1988). Sediments and nutrients in the outflow alter the competitive balance of the reef system by physically inhibiting coral growth and by encouraging algal growth in the higher nutrient conditions. This can lead to significant changes in landscape structure, which can be further accentuated by additional biotic interactions.

There has been concern recently about the impact on reef structure of outbreaks of the crown-of-thorns starfish (*Acanthaster planci*). Heavy grazing by this key species leads to dramatic short-term changes in the reef landscape, although it does appear that reefs eventually recover to more or less their previous condition. It has been argued that these outbreaks may be associated with the influx of additional nutrients to the reef (e.g. after shoreline clearance or heavy rains) which leads to plankton blooms, which in turn lead to increased survival of *Acanthaster* larvae (Birkland 1982). The outbreaks of crown-of-thorns starfish may be an extreme fluctuation in the complex control systems of coral reef structures where echinoid grazers control algal growth that would otherwise reduce coral recruitment and success (Mann 1982; Sammarco 1982). Any change in the populations of either the grazers or the algae (e.g. from nutrient inputs, hurricanes, overfishing or predators on the grazers) can set in chain a series of abiotic and biotic interactions leading to changes in biodiversity and landscape structure (Ogden and Lobel 1978; Wiebe 1988).

The role of sea otters (*Enhydra lutris*) in shaping the 'landscapes' of kelp communities has been well documented (see also 6.1.9). Otters feed on a range of benthic herbivores and in particular on sea urchins. In areas where otters were hunted to extinction, urchin populations exploded and overgrazing of the macroscopic algae led to a spatially heterogeneous community in which kelp was a minor component. Otters have been reintroduced into some areas and there is evidence of a shift towards a much less diverse community dominated by a single kelp species (Duggins 1980). The effect of otters on community is not only via their direct predation on herbivorous species but also via their discarded clam shells and their excavation of soft-bottom areas for clams. These activities leave more shells on the surface and these are a more favourable location for the establishment of kelp in soft-bottom environments (Kvitek *et al.* 1992). It is also possible that in the past the presence of otters led to high algal productivity which in turn supported the presence of sea-cows (*Sirenia* spp.). Sea-cows have a major effect on sea grass bed by their 'ploughing' feeding action. In the northern Pacific, Steller's sea-cow (*Hydrodamalis stelleri*) was also hunted

to extinction, so that the reintroduction of sea otters in this region may not lead to the recovery of communities or landscapes similar to those before the impact of over-exploitation (Dayton 1975; Mann 1982).

The loss of mangroves from shorelines also reduces the effectiveness of their filtering (or absorbing) the energy of wave action thus exposing coastlines to major landscape modification (see 6.1.11). There are many similar examples of where the loss of a few key filtering species from estuarine or sand-dune systems can lead to changes in landscape structure.

The water body of open oceans is patchy at various scales (Steele 1991). However, the patches tend to be associated more with physical phenomena, such as circulation cells, than with biotic phenomena. One possible exception is the effect of large floating mats of raft weed, such as *Sargassum*, which may decline due to pollution and cause changes in ocean structure (see 6.1.12).

In freshwater systems the vegetation of the riparian zone also has an energy-absorbing role. Streamside vegetation and fallen logs dissipate stream energy and trap sediment. The loss of these species either through direct human action such as clearing, or indirect action such as small changes in water flow and flooding patterns with dams or weirs causing changes in streamside and floodplain vegetation, can lead to major changes in the flow regime of the stream itself and to changes in its path (Naiman and Décamps 1990; Malanson 1993). In general, the loss of vegetative cover in mountainous topography will lead to wider, shallower valley systems with a more uniform gradient (Waring and Schlesinger 1985). The effect of the loss of large mammals on stream and wetland habitats has already been described for beavers and hippopotamuses.

6.2.5.3 Generalizations

It is often difficult to determine whether changes in landscapes are due to changes in biodiversity *per se* or to

the processes that led to the changes in biodiversity. Even when changes in landscape structure can be linked to a biotic factor, the changes are often set in course by the gain or loss of a single key species.

Table 6.2-2 summarizes the examples presented in this review. The examples are by no means comprehensive but we suggest that they are indicative of the relative importance of the different ways in which biodiversity is linked to landscape structure across different biomes. The mechanisms are defined as ‘filtering or concentrating’, where organisms act primarily as physical barriers or conduits in transferring materials between landscape elements; ‘disturbance regimes’ where organisms are instrumental in propagating energy (or sometimes materials) between landscape elements; and ‘key species’ where one or a few species can directly bring about changes to landscape elements that eventually lead to changes in landscape structure.

There are a few generalizations that may be made from this review. The role of key species in triggering changes that alter landscapes is common to all biomes. Sometimes the loss or invasion of the key species is accompanied by consequential changes in biodiversity and these are the basis of changes in landscape structure and functioning (e.g. sea otters in kelp forests); in others the impacts of the key species are concentrated more directly on the landscape (e.g. elephants and hippopotamuses) which, in turn, may lead to changes in biodiversity.

Nutrient (including water) concentration and filtering effects are most important in biomes with low concentrations of nutrients. Thus, we observe changes in landscapes in arid and savannah systems as a result of the disruption of the nutrient and water concentration processes and in coral reef communities changes in communities and landscape functioning when filtering systems break down and higher concentrations of nutrients reach the reef.

In higher productivity systems changes in disturbance regimes, and particularly fire regimes, tend to be more

Table 6.2-2: Summary of the examples cited in this chapter classified by the types of changes in biodiversity and by biomes. There is a question mark against the tick under tropical forests because this refers to rain forest patches embedded in a wet-dry tropical woodland.

	Arid	Savannah	Temperate forest and grasslands	Tropical forests	Aquatic (freshwater, estuarine and marine)
Altered material concentration or filtering	✓	✓			✓
Altered disturbance regimes		✓	✓		
Key species effects	✓	✓	✓	✓?	✓

important processes in modifying landscapes. In the most highly productive and diverse communities (i.e. tropical rain forests) changes in biodiversity appear to have little effect on landscapes. In these systems disturbances must be of large spatial or temporal scale in order to disrupt the nutrient and water cycles and thus have long-term effects on landscape structure.

6.2.6 Biotic linkages and ecosystem functioning

6.2.6.1 Introduction

In this essay, biotic linkages are considered as an ecosystem functional property in their own right. Thus a major emphasis will be placed on discussing the roles of biodiversity in biotic linkages and community structure, specifically exploring how these are disrupted by human activities. In addition, an attempt will be made to discuss further how biotic linkages may in turn influence some of the other more conventional ecosystem properties (e.g. nutrient cycling, primary production, microbial activities) reviewed in Section 5 of the GBA. In this analysis, however, it is important to bear in mind the following caveat. The roles of biodiversity in biotic linkages and species interactions are difficult to assess since changes in species richness (i.e. deletions/additions) imply consequent changes in linkages and therefore it is difficult to assign causality for the observed effects unequivocally. An appropriate assessment, for the future, would require different approaches, such as assessing effects as a result of changes in the strength of interactions without changing species richness.

Occasionally, biological interactions may have discernible direct benefits to humans, as described in Box 6.2-1.

The biological activities of one individual invariably impinge upon the activities of other individuals of the same or different trophic levels, and the magnitude and direction of these effects are commonly referred to as biotic linkages or species interactions. Though activities occur at the level of the individual, typically the individual interactions are grouped according to their species designation (i.e. intra- or interspecific). According to their sign, these interactions can be classified into two broad groups – antagonistic and mutualistic — and can be further classified into many kinds of more specific interactions, most of which are described and treated in text books of ecology (e.g., Begon *et al.* 1993; Ricklefs 1993).

Most species are involved in several interactions with other species and each interaction can differ in its sign (antagonistic, mutualistic), magnitude (strong, weak),

specificity (ranging from complete specialism to generalism), and degree of dependence on interacting organisms (obligate, facultative). The multiple interactions of species imply that most communities consist of a pattern of interactions among their member species that we refer to as a community web (this differs from a food web, which focuses on trophic links among species). This implies that besides direct interactions there are complex indirect or non-linear interactions among species (e.g. a top predator that feeds on a polyphagous herbivore which in turn determines relative competitive interactions among plants). Effects, consequently, are usually non-linear. The impact of a single species on a community is therefore a complex function of the number of interactions, the signs and magnitudes of those interactions, and the number of indirect links with other species in the community. This complex function can be referred to as the average strength of a species interaction with its community, and this strength can range from strong in keystone species (see Terborgh 1986) to weak in relatively independent species. A more detailed discussion of the contrasts between direct and indirect interactions and non-linearities is given by Menge (1995) and in Box 5.2-1. Although there is still an ongoing debate about the relative importance of types of interactions, or of keystone species, and about the role of compensations among species within functional groups, particularly in terrestrial biomes (see reviews in Ricklefs and Schluter 1993), there is a consensus that biotic interactions play a crucial role in structuring communities. This is particularly highlighted in studies of coastal benthic communities, where experimental manipulation has been actively applied, leading to a mechanistic understanding of such details and to a clarification of the importance of biotic linkages and species interactions for community structure and composition (see a recent review in Menge 1995). However, there is still a major gap in the knowledge needed to assess to what extent community structure in turn affects ecosystem functioning. Here we attempt to review (1) how changes in biodiversity (largely due to human activities) in different biomes affect biotic linkages or species interactions and, to the extent that the scant information permits, (2) how this scales up to alterations of ecosystem functioning.

6.2.6.2 Human impacts

Human activities produce alterations of biodiversity that directly or indirectly affect the patterns of interactions and linkages of species to one another in communities. In Arctic and subalpine systems, overhunting and overharvesting of marine and terrestrial mammals is leading to population declines (6.1.1). When these animals are keystone or top predators (e.g. sea otters), the effects seem to alter dramatically the pattern of interactions and may propagate to the entire ecosystem. Likewise, herding

Box 6.2-1: Potential human benefits of the *Urania/Omphalea* coevolution.

The day-flying moth *Urania fulgens* and its host plants *Omphalea* spp. provide a remarkable example of the complex and fascinating ways in which elements of biodiversity (viewed at the species level in this case) operate in their natural settings, as well as the potential implications these seemingly obscure organisms may have for human society.

The adult moths migrate northwards and southwards between several localities in northern South America and southeastern Mexico. In many of these localities, with a certain periodicity, they undergo dramatic local population explosions. The caterpillars of this moth feed exclusively on the foliage of plants of the genus *Omphalea*, such as the vine *O. diandra* in Panama, or the 25 m tall tree *O. oleifera* in Mexico. During years of the moths' population explosions, these plants are heavily defoliated. If fed with the leaves of other plants, the caterpillars will not eat, and starve to death. In the Mexican populations this was found to be the case, consistently, even if the moths were fed with all the local species of the same family as *Omphalea* (Euphorbiaceae). The *Omphalea* plants, in turn, are rarely eaten by herbivores (either invertebrates or vertebrates in the Mexican situation) other than *Urania*. This high degree of mutual specialization indicates a long joint evolutionary history, of the type usually referred to as coevolution. In addition, it has been noted that the moths' migrations and the magnitude of their population explosions appear to occur with a certain periodicity – but the underlying mechanisms for this are not fully understood.

Such tight biotic interaction appears to be mediated by some peculiar metabolites (apparently toxic to many animals) that were unknown until very recently, and which are present in the plants' tissues and can be sequestered by the caterpillars without them, in turn, being affected. Specifically, it has been found that *O. diandra* produces and *U. fulgens* concentrates dihydroxymethyl-dihydroxypyrrolidine (DMDP). These remarkable compounds have been found to be quite promising in three aspects of relevance to humans. The first of them has to do with AIDS, due to their role in blocking the activity of the HIV virus. Secondly, DMDP suppresses enzymatic activity in *Callosobruchus* beetles. The beetles attack stores of beans in the tropics; and as a result of the differential effect of the chemical, humans can eat beans treated with DMDP (which the beetles would not have been able to eat). Thirdly, it has been found that DMDP also has some activity against cancer and diabetes. Such remarkable activities of these metabolites and the moths' ability to deal with them constitute promising avenues not only for the prospecting and development of new drugs, but also for the understanding and possible application of novel detoxifying mechanisms.

On the other hand, based on the understanding of the activity of the plants' toxic metabolites, some evidence suggests that the periodicity of the migrations and the magnitude of the moths' population explosions might be governed by the time it takes for the heavily defoliated plants to induce and relax the production and build-up of their toxic compounds.

Given the migratory habits of the moth and the great specialization of their ecological interaction with the *Omphalea* plants, this system highlights two points pertinent to biodiversity conservation: that conservation efforts should not be directed only to biodiversity components (e.g. species) *per se*, but also to their underlying ecological and evolutionary processes (such as biotic linkages) and to the global nature of the conservation/disruption of biodiversity. In this system, for example, perturbations in a given locality (say Mexico) may dramatically disrupt the ecological interactions and destroy a complex ecological process in another distant locality (say Panama) and vice versa.

practices or changes in reindeer abundance change lichen cover and vegetation structure (Andreev 1978). In tropical forests, habitat destruction (deforestation, forest fragmentation) and contemporary hunting (6.1.2) produce dramatic alterations of biodiversity components which are beginning to show consequences in biotic interactions such as pollination (Aizen and Feinsinger 1994) and herbivory (Dirzo and Miranda 1991). Temperate forest systems show a marked vulnerability to species introductions of

pathogenic pests such as the ones causing Dutch-elm disease and chestnut blight, or insects such as the gypsy moth (6.1.3). In arid lands, both importation of non-native plants and removal of native ones are occurring actively in association with forage improvement plans (6.1.4). Human activities are also leading to the decline of bat populations, which in turn affects the pollination pattern of *Agave* plants in North American deserts (Howell and Roth 1981). Introduction of mammals and other changes in grazing

regime cause marked alterations of the vegetation structure and composition and plant-plant interactions in savannahs (6.1.5), boreal forests (6.1.6) and temperate grasslands (6.1.7). Species introductions and habitat modification are argued potentially to disrupt biotic interactions such as pollination and dispersal (6.1.8). In aquatic biomes the removal or partial displacement of predators by overfishing, overcollecting or pollution, as well as the introduction of new species can produce considerable effects (particularly well documented in coastal systems – see 6.1.9) which can propagate to the rest of the ecosystem by means of the disruptions of biotic interactions.

From the point of view of the relevance of biodiversity with regards to biotic linkages, the effects of human activities can be assessed more simply in terms of species deletions or species additions.

6.2.6.3 Effects of removal of species on biotic linkages

The removal of a species from a community may cause further losses and therefore profoundly affect biotic linkages, or it may cause no further losses (although all the other persisting species may do so at different densities) thus leading, at least theoretically, to what Pimm (1986) calls the species deletion stability of systems. Within a web, species deletion stability may vary considerably, depending, among other things, on the species richness of the system, the trophic level from which the species are removed, and the degree of connectance of the species removed (connectance being the actual number of species interactions in a food web divided by the number of possible interactions (Pimm 1986). Studies of model communities suggest that species-rich communities (i.e. those with high connectance) are more sensitive to the loss of top predators while the loss of primary producers and consumers has less of an effect on community dynamics (Pimm 1986).

Field data show that most natural systems, regardless of species richness, appear to be changed after the removal of top predators or herbivores. This conclusion appears to hold for a wide variety of biomes including marine and freshwater systems (Pimm 1980), East African savannahs (McNaughton 1985), desert communities in North America (Brown 1985), and tropical forests (Terborgh 1988). In an excellent experimental study McNaughton (1977) found that the consequences of the removal of herbivores depended upon species richness: plant species composition changed more when a grazing herbivore, the African buffalo, was excluded from a species-rich grassland, than when the same herbivore was excluded from a species-poor one. No explicit experiments seem to be available to assess the consequences of the removal of plant species from species-poor and species-rich systems. Although species-rich systems might be expected to be more resistant to the loss of plant species, the occurrence of keystone plant

species such as *Ficus* spp. in highly diverse tropical forests (see Terborgh 1986), suggests that removal of certain plant species can indeed have profound effects on species composition and linkages in the rest of the web. In summary, the outcome of alterations in the web of interactions is very much dependent on the complexity of the web and the identity (e.g. keystone status) of the species.

6.2.6.3.1 Empirical evidence of the effects on ecosystem functioning. Apart from the alteration of biotic linkages and community structure due to species removals, consequences can be seen at the level of ecosystem processes. For example, the native moose, *Alces alces*, on Isle Royale, Lake Superior, Canada, feeds preferentially on early successional species, avoiding those of late successional stages (Pastor *et al.* 1993). Thus herbivory determines the structure and composition of these forests. By comparing browsed and unbrowsed plots, it has been shown that this herbivore significantly reduces nutrient availability and microbial activity and, in the longer term, primary production and successional trends.

A 12-year study by Brown and Heske (1990) showed that the removal of three seed-eating kangaroo rat species caused habitats to shift from desert to scrub to arid grassland. While not documented by the authors, such dramatic alterations in plant species composition should lead to considerable changes in the amount and chemistry of leaf litter, decomposition rates and nutrient cycling. Thus, seed predation appears largely responsible for determining the type of community in this system and therefore may control a wide range of ecosystem-level processes.

6.2.6.4 Effects of addition of species on biotic linkages

Food web theory argues that, on average, communities seem to be highly resistant to species introductions (Pimm 1986). Nevertheless, there seems to be good evidence to suggest that species richness affects the susceptibility of a community web to ecological invasion (introduction of non-native species). In general, it appears that species-rich tropical forests are very resistant to invasions (see 6.1.2). Diamond (1985) found that the rate of success of bird introductions on tropical and subtropical islands declines steeply with the species richness of the extant native avifauna. An extrapolation of these findings would suggest that temperate biomes (with lower species richness) should be more susceptible to species invasions. Data for insect introductions suggest a similar pattern (see a review in Pimm 1986), but prediction of the success of insect introductions from a knowledge of the community structure and diversity is still somewhat debatable. Other noticeable patterns involve the apparent susceptibility of islands to invasions (related in some instances to species diversity) and the

subsequent (in some cases devastating) effects of such invasions on the rest of the biotic linkages.

6.2.6.4.1 Empirical evidence of the effects on ecosystem functioning. Aside from the question of the role of species diversity in susceptibility to invasion, there remains the issue of the possible consequences of such additions to some ecosystem functions or properties. The following examples indicate such potential ecosystem consequences. The Argentine ant (*Iridomyrmex humilis*) has invaded extensive areas of the world causing considerable changes in the species interactions of the invaded systems. In the South African Cape Region it has radically altered the composition of the native ant fauna by replacing dominant species. Bond and Slingsby (1984) documented the consequences of this invasion for the mutualistic interactions between plants and seed-dispersing ants. They found that, compared to the native ant species, the Argentine ant was much slower to discover the seeds of an exclusively ant-dispersed plant, dispersed these seeds shorter distances, and failed to store them below ground where they would have gained protection from seed predators. Given the importance of ant seed dispersal in this system, the invasion of such an influential ant species has the potential substantially to alter community composition and ecosystem-level processes.

The inadvertent introduction of the house mouse to Marion Island in 1818 resulted in substantial alterations in decomposition and nutrient cycling on the island (Crafford 1990). This introduction was found to be particularly influential because the mice preferentially feed on the island's dominant detritus-feeding invertebrate, the endemic moth *Pringleophaga marioni*. Larvae of this moth are estimated to consume up to 50% of the primary production on the island. Such processing considerably enhances microbial activity and subsequent release of essential nutrients. Some experiments (Crafford 1990; Smith and Steenkamp 1990) have shown that the addition of just two moth larvae into litter stimulated mineralization of nitrogen ten-fold and phosphorus three-fold. Thus, these moth larvae appear to be the primary mediators of nutrient mineralization and introduction of an exotic predator has greatly altered ecosystem processes on this island.

6.2.6.5 Cross-biome comparison and ecosystem services

In an attempt to summarize the available information in a way that permits us to highlight the effects of human activities on biodiversity components, and the consequences of this on biotic linkages, we present a cross-biome comparison based on a distillation of several published accounts that provide information on (1) the kinds of biomes that are likely to be affected by the modification documented; (2) the interaction type; (3) the biotic hierarchical level at which it operates (e.g. gene, individual, population, species, community, ecosystem,

landscape, region, global); (4) the human activity responsible for the change; (5) the ecological effect, and (6) the human consequences. The working set consisted of 11 examples of mutualistic and antagonistic interactions which included cases applicable to specific biomes and cases applicable to all biomes (Table 6.2-3).

6.2.6.5.1 Pollination linkages. This review indicates that landscape modification in the form of partial deforestation and habitat fragmentation affects pollination linkages in a variety of terrestrial biomes, from temperate sandy meadows (Jennersten 1988) to tropical forests (Karr 1982). Thus it appears that pollination disruptions occur across most biomes except in aquatic ones, where biotic pollination *per se* is poorly represented. The alteration of this type of biotic interaction occurs largely due to the reduction of species or abundance of pollinators. The consequences of this disruption range from potential local extinction of plant species to reduced genetic variation in partly self-compatible outcrossers which thus depend to a larger extent on self-pollination (Jennersten 1988). The consequences of reduced genetic variation can in some cases scale up to ecosystem functions and affect a given service. For example, in agroecosystems, where single hybrids are planted over large areas, pests and pathogens can be devastating. The outbreak of *Helminthosporium maydis* on the CMS hybrid corn (Williams and Levings 1992) is an outstanding example of the consequences of reduction in biodiversity (genetic variance in this case) which affects biotic linkages and in turn affects an ecosystem function and service (the regulation of production).

6.2.6.5.2 Seed dispersal linkages. Deforestation and fragmentation lead to the loss/decline in abundance of some species of frugivores in tropical forests, which in turn have the potential to reduce biotic seed dispersal (Kattan 1992). The greater occurrence of plant modifications for biotic dispersal in terrestrial tropical and temperate deciduous forests (Howe and Smallwood 1982) suggests an expected trend of greater importance of this biotic linkage in such biomes than in more dry and aquatic ones. A similar trend could be expected in the case of defensive mutualisms, though appropriate information for cross-biome comparison is very limited. The expected consequences of reductions in such mutualisms as frugivory may include reductions in the reproductive capacity of highly dependent (specialized) plants, or reductions in genetic variability (similar to the case of pollination described above) though no information seems to exist regarding the ecosystem-functioning consequences.

6.2.6.5.3 Grazing linkages. Modifications of grazing regimes dramatically affect several ecosystem processes in a variety of both terrestrial and aquatic biomes (Table 6.2-3). Additions or deletions of top predators alter the abundance or occurrence of herbivores and this in turn may

Table 6.2-3: Effects of human activities on biodiversity components.

Interaction	Species	Human Activity	Effect	Potential consequence	Biodiversity hierarchy	Applicable biome	Source
Pollination	Several	Landscape modification (habitat fragmentation)	Reduction of pollinator efficiency	Inbreeding local extinction	Gene-landscape	Terrestrial	1, 2
Grazing	Ungulates	Simplification of herbivore guild, overgrazing	Change in vegetation structure and composition	Desertification	Spp.-landscape	all	3
Predation-grazing	Otters	Eliminate top predator	Overgrazing by urchins	Local extinction of algae	Gene-landscape	all	4
Predation-grazing	Nile perch	Addition of top predator	Loss of grazers	Spp. extinction collapse of fisheries	Spp.-landscape	all	5
Predation-grazing	Beaver	Deletion of keystone sp.	Loss or disturbance	Homogenization of habitat	Landscape	all	6
Predation-grazing	“	Addition of keystone sp. (Chile, Argentina)	Increased disturbance	Disruption of habitat	Landscape	all	7
Predation-grazing	Fish	Deletion of zooplankton grazers	Phytoplankton bloom	Ecosystem collapse	Gene-landscape	all	8
Dispersal	Birds	Deforestation fragmentation	Reduction of dispersal agents	Reduced reproductive potential of plants	Gene-spp.	Moist:wet >dry forests	9
Dispersal	Argentine ant	Introduction of exotic sp.	Excluded native ants	Reduced reproductive potential of plants	Extinction	Terrestrial	10
Predation	Mouse/moth	Addition of top predator	Extinction of prey (keystone detritivore)	Potential disruption of detritus pathway	Gene-ecosystem	all	11
Predation	Cats	Deletion of top predators in tropical rainforest	Mammalian herbivores increase	Overgrazing, excessive seed predation, change in vegetation structure and composition	Gene-spp.	all	12
Predation	Lamprey	Addition of top predator (building of dams)	Locks bring predator and prey together which results in extinction of prey (fish)	Collapse of fisheries	Gene-spp.	all	13

have a range of effects from modifications of vegetation structure to disruptions of detritus pathways. This type of ecosystem function consequence occurs in several forest biomes from boreal to tropical ones, as well as in aquatic ones. The introduction of exotic species affects trophic relationships and a number of biotic linkages (predation, herbivory, hierarchical competitive relationships) in non-linear ways and this type of effect is known for both aquatic and terrestrial biomes of several types. Some of the best-known examples are referred to in Table 6.2-3.

6.2.6.6 Conclusions

Although there is little specific documentation about the importance of biodiversity components affecting biotic linkages and then ecosystem processes, our review of the available information indicates that a common outcome of human impacts on biotic linkages is alteration of the stability of community structure (pattern of interactions) and composition (distribution and abundance of species). From our analysis, it appears that in low-diversity systems, the full set of species within functional groups is important. This is the case in boreal forests (Pastor *et al.* 1993) and temperate rocky intertidal shores (6.1.9), while it appears that in high-diversity systems (e.g. tropical forests, tropical rocky shores) the deletion of species can be compensated for by the other species in the available pool. However, compensation does not seem to occur when deletion of a whole functional group takes place, even in high-diversity systems (e.g. the deletion of the guild of understory herbivorous mammals in tropical forests; Dirzo and Miranda 1991).

The present assessment allowed us to consider the certainties and uncertainties of how changes in biotic interactions affect community stability (cf. Orians 1982). We conclude that stability changes occur when biotic interactions and linkages are altered through deletions, additions or other alterations of structure — and that the effects can range from reductions of genetic variability to landscape-level effects and from moderate to catastrophic. Effects are generally confined to within ecosystems or biomes and there is little evidence of them scaling up to geographically distant biomes. However, an example of the potential of the latter can be drawn from the case of across-biome migratory organisms such as birds or insects. Deforestation and habitat fragmentation in tropical forests affect several species of migratory birds, which in turn may affect biotic interactions involving these birds in temperate forests. The alterations of temperate forests may have similar effects in tropical forests.

Much of the available evidence demonstrates that changing biodiversity changes biotic interactions and links in communities, but this is evidence that is generally gathered *after* alterations have occurred. Effective prediction and management modelling is dependent upon

further research involving the experimental manipulation of species, through natural and planned experiments.

indispensable activities in the circulation of matter, on which all larger organisms, including humans, depend (Hawsworth and Colwell 1992; Guerreo and Pedros-Alio 1993; Allsopp *et al.* 1995). Primary production, decomposition, nutrient recycling, trace gas production and the other processes considered in the preceding chapters either have a microbial component or are carried out only by microorganisms.

Microorganisms occupy a greater range of ecological niches than macroorganisms (Price 1988) and some groups were diverse as long ago as 3.5 billion years (Schopf 1993). They occur in all niches where life is thermodynamically possible, including many extreme environments in which no other life is found: high temperatures (80–110°C), high salinity (e.g. the Dead Sea, >320 g salt/litre), high pressure (deep ocean hydrothermal vents, >600 atm), very acid (below pH 2), low water activity (under 0.65 aw) and extreme cold (e.g. cryptoendoliths in Antarctica, with photosynthesis at –8°C) (Vestal and Hobbie 1988; Edwards 1990).

Microbial diversity does not represent a monophyletic group, but includes archaea, eubacteria, fungi, algae, protozoans and viruses. In practice, microorganisms are species either belonging to a phylum many members of which cannot be seen by the unaided eye, or where microscopic examination, and in many cases growth in culture, is essential for identification. Culturing, however, reveals only a biased subset of the species present in natural systems and may not accurately reflect either the actual composition or the activity of microbial communities (Hobbie and Ford 1993). New techniques (White *et al.* 1991) are beginning to rectify this problem in many ecosystems, including oceans (Giovannoni *et al.* 1990), coral reefs (Rowan and Powers 1991, 1992), hot springs (Ward *et al.* 1990; Barns *et al.* 1994) and hydrothermal vents (Hedrick *et al.* 1992). However, they are also uncovering whole groups of previously unknown organisms (DeLong *et al.* 1994, Olsen 1994: oceanic archaeobacteria; Sherr and Sherr 1991: ultraplankton). Perhaps fewer than 5% of microbial species have been discovered and named (Hawsworth 1991; Hawsworth and Ritchie 1993; Trüper 1992; see Section 3.1) and in many cases their precise ecological and biogeochemical roles are unclear (Hobbie and Ford 1993).

Our task is to describe how this dramatic and relatively unknown diversity influences a huge range of ecosystem processes and to elucidate how it might be threatened by anthropogenic activities.

6.2.7 Microbial diversity and ecosystem processes

6.2.7.1 Background

Microorganisms are crucial to the functioning of every ecosystem on Earth. They perform unique and

6.2.7.2 Important aspects of microbial diversity

Due to a limited set of morphological traits identifiable in microorganisms, microbiologists have commonly classified organisms according to detectable metabolic substrates and end products, by trophic categories, or by size. In some

ways, such functional groupings put us closer to an understanding of the roles of microbial diversity in ecosystem processes than for other groups of organisms. To say that functional group diversity is important to ecosystem processes is circular – known groups are classified as such *because* of their importance to the process at hand (Vitousek and Hooper 1993). The task is to discern what the important groups are and how they interact with each other and with abiotic controls.

6.2.7.2.1 Substrate-based groups. The functional diversity of microbes, particularly as defined by the substrates used for energy metabolism (both electron donors and -acceptors), is integral to our understanding of biogeochemistry. Substrate linkages between microbial functional groups form the basis of element cycling (e.g. N-fixers, heterotrophs, nitrifiers, denitrifiers: Meyer 1993; sulphate/sulphur reduction and sulphur/sulphide oxidation: Howarth and Stewart 1992; Meyer 1993). In some cases, as in oxic/anoxic sediment interfaces (Schlesinger 1991; Andrae and Jaeschke 1992), microbial mats, and hydrothermal vents (Hedrick *et al.* 1992), multi-organism redox cycles can be relatively localized and major transitions between groups take place over very short (millimetre) distances. At the other end of the scale, through trace gas production frequently due to metabolic redox reactions, microbes shaped the composition of the atmosphere and currently play a significant role in its maintenance (Hedrick *et al.* 1992; 6.2.4).

Vast complexity exists within the broadly defined redox groups. Within the wide range of aerobic heterotrophic microbes, the importance of further substrate specialization is frequently cited for carbon metabolism during degradation of plant material (e.g. specialists on lignin, cellulose, pectins; Garland and Mills 1991; Meyer 1993; Schimel 1994; Zak *et al.* 1994). Even within the group that decomposes lignin, however, metabolism of this recalcitrant plant compound is carried out by hundreds of species of fungi (even at a single site) and by bacteria of several genera (Meyer 1993). These can occur in succession and may be attacking different ligno-cellulose bonds, so we cannot necessarily assume 'redundancy'. Some transformations, such as nitrification and sulphate reduction, require multiple groups to complete the process (ammonium oxidizers and nitrite oxidizers, sulphate reducers and sulphur reducers, respectively). Some functional groups form consistent taxonomic groups (e.g. the nitroso-bacteria in ammonium oxidation) or at least share common metabolic constraints (sulphur-oxidizing bacteria). Others, such as denitrifiers, are very diverse with different substrate specificities and share only the use of either nitrate or nitrite as electron acceptors in a facultative anaerobic metabolism (Cook and Kelly 1992; Meyer 1993). Again, the importance of these functional groups is widely acknowledged in that loss of an entire group would lead to

loss of a process and potential disruption of the entire cycle. We know almost nothing, however, about whether or how diversity within groups might contribute to process rates, process stability, or the types of processes that are active. Though it is a common assumption (used in this assessment as well) that more diverse groups are less sensitive to disruption, this warrants empirical verification.

6.2.7.2.2 Size-based groups. Functional group classifications based on size are important particularly in aquatic food webs. The relatively recent discovery of nano- (2–20 μm), pico- (0.2–2.0 μm), and even femtoplankton (0.02–0.2 μm) has changed our understanding of energetics and nutrient cycling in both marine and freshwater systems (Sherr and Sherr 1991; Steinberg and Geller 1993). The classical aquatic food chain from diatoms to metazoans to small fish to large fish holds only for pieces of a more complex web. The size-class microbial groups are both taxonomically and trophically diverse, including photoautotrophic and heterotrophic prokaryotes and eukaryotes. Mixotrophs abound and feeding is based as much on the relative sizes of predator and prey as on classical trophic categories of primary producers, herbivores and predators (Sherr and Sherr 1991). Consequently, large fractions (20–60%) of primary production are cycled through 'microbial loops' with no link to macrofauna due to the energetic losses at trophic stages too small to be consumed by metazoans (Pomeroy and Wiebe 1988; Pomeroy 1991; Sherr and Sherr 1991).

In these loops, not unlike terrestrial ecosystems (e.g. Clarholm 1985; Jackson *et al.* 1989; Schimel *et al.* 1989), bacteria compete with primary producers (larger phytoplankton) for nutrients, rather than just serving as nutrient regenerators themselves, and grazing on bacteria is responsible for large amounts of nutrient regeneration (Pomeroy and Wiebe 1988; Pomeroy 1991; Goldman and Dennett 1992). The rapid nutrient recycling provided by the aquatic microbial loop leads to relatively stable primary production in oligotrophic systems. In such systems, the microbial pathway is favoured because low nutrient concentrations give a competitive advantage to smaller individuals (i.e. higher surface to volume ratios; Pomeroy 1991). As nutrient concentrations increase, as in seasonal lake turnovers or areas of oceanic upwelling, larger phytoplankton are favoured. These in turn are fed on by metazoans and those are subsequently eaten by fish. Due to the life-cycle constraints of metazoans, however, their growth frequently lags behind that of the blooming algae, whose populations become nutrient-limited and crash (Pomeroy 1991; Sherr and Sherr 1991). Thus, trophic diversity within the size-based groups leads to alternative pathways for nutrient and energy flow, and diversity among size-based groups results in different patterns of primary production (stable vs boom and bust) in response to the bottom-up controls of nutrient availability. Nutrients may

regulate the total productivity of some systems, but species characteristics (size, competitive abilities) regulate the relative amounts that flow to larger metazoans and fish. As with the redox functional groups, knowledge of the roles of individual microbial species is rare at best.

6.2.7.2.3 Species-specific interactions. When a single species has a strong effect on ecosystem processes, that species may be looked upon as a functional group with only one member. For example, for an exotic species to alter ecosystem processes, Vitousek (1986) lists the following criteria: that it must acquire or use resources differently from native species, that it must alter trophic structure, or that it must alter disturbance regime. The clearest cases of such effects for microbial species (whether invaders or not) are in species-specific interactions. The importance of individual microbial species is much better known for effects on economically important organisms, as for both mutualists and pathogens in agroecosystems, than for carbon and nutrient cycling in natural systems, particularly given the problems of identification discussed above. Microbial mutualists and pathogens, however, can have important ramifications in structuring natural ecosystems as well (e.g. N-fixing in primary succession and mycorrhizal associations: Vitousek and Walker 1989; Galloway 1992; Dhillon and Zak 1993; Read 1993; Schimel 1994; Chestnut blight (*Cryphonectria parasitica*), *Myxoma* virus, *Phytophthora cinnamomi*: Burdon 1993; Dobson and Crawley 1994; Castello *et al.* 1995). In cases with dramatic ecosystem level effects, both novel characteristics of the organisms involved and the specificity of the biotic interactions are relevant aspects of biodiversity.

6.2.7.2.4 Qualitative and stabilizing effects of diversity. Two important ways in which microbial diversity (and biodiversity in general) can affect ecosystem functioning are (1) qualitative effects, as with different functional groups (Chapin *et al.* 1994); and (2) stabilizing effects (cf. McNaughton 1977; Tilman and Downing 1994), as with diversity within functional groups. The sensitivity of ecosystem functioning to environmental change (anthropogenic or otherwise) becomes a question of the presence/absence of basic functional groups, the strength of control exerted on a given process or interaction, and the plasticity of organisms within groups to operate over a range of conditions. While many soil and aquatic bacteria are widespread, it is a myth that all microorganisms are distributed ubiquitously. Those that are restricted to special environments (e.g. isolated hot springs) or lack broad dispersal (many fungi, especially lichen-forming species) may not recolonize easily if they are lost from an ecosystem. Some of these, such as mycorrhizas, play key roles in the re-establishment of systems following disturbance (Perry *et al.* 1987, 1989; Dhillon and Zak 1993). At the same time, we have only very limited

knowledge of the identity and functional attributes of the myriad microbes found in even one gram of soil (see 6.2.2). Predictions of the strength of control are most easily and frequently based on abundances, though 'keystone' organisms/groups are often not recognizable on this basis. Predictability is a major problem, especially in microbial communities, as we often are not aware of species' roles as keystones until they are either lost from systems or introduced as invaders (Sherr and Sherr 1991; Bond 1993). For microbial groups whose members are cosmopolitan and whose activity depends on environmental conditions, ecosystem-level processes carried out by more diverse groups will probably continue as conditions change, but may be carried out by different organisms (Hobbie and Ford 1993). Of course, when conditions cross certain critical boundaries (as in going from aerobic to anaerobic), different organisms and processes may become active while others become inactive. The problem is the identification of the boundary conditions and rate changes through that spectrum of conditions and microbes. Thus, microbial diversity (and biodiversity in general) could be important in the sense that either (a) process rates are stabilized through a variety of environmental perturbations because of compensatory changes in community composition (cf. McNaughton 1977; Tilman and Downing 1994), or (b) process rates change as the species performing them change, due to differences in the functional properties of the organisms. In the first case, diversity is thought to be important for maintaining consistency (stability and/or resilience) in ecosystem properties/process; in the second case, it is seen as important for helping to create or maintain ecosystem heterogeneity through functional differences, (cf. Chapin *et al.* 1994; Schimel 1994). These seemingly contradictory statements point out the need to be precise about the expected ecosystem-level effects of diversity when addressing hypotheses on this topic.

The predictions may, in fact, not be contradictory, but just opposite ends of the perturbation spectrum. Shifts in dominance within a diverse extant community may stabilize processes over a relatively narrow range of environmental conditions; if changes are long enough or strong enough, however, and if appropriate organisms are present or can colonize, entirely different communities with different functional properties may become established (e.g. shifts in phytoplankton dominance with changes in nutrient availability).

6.2.7.3 Changes in biodiversity and microbial activity

Using the criteria of specificity of interactions, sensitivity to disturbance/change, and diversity within functional groups, we can recognize microbially mediated ecosystem processes sensitive to changes in biodiversity and those in which, in addition, anthropogenic forces have affected or may affect microbial diversity (Table 6.2-4). The biome

types (Chapter 6.1) in which occur both the anthropogenic forces and the microbial processes that are sensitive to those forces are also identified. In many cases, the reason for the biome listing is the prevalence of a particular type of disturbance; absence of a biome from the listing should not be taken to imply that it is necessarily resistant to that threat.

6.2.7.3.1 Biotic interactions. Species-specific biotic interactions, both mutualistic and pathogenic, are the most vulnerable to changes in microbial composition and diversity. The gain or loss of a microorganism involved in a mutualistic or pathogenic interaction can have consequences that range from subtle changes in competitive ability of the host species to the loss of populations or whole communities of macro-organisms. What makes an ecosystem process particularly susceptible to change, however, is difficult to predict. If only one or a few species of microorganisms are responsible for a mutualistic or pathogenic interaction of importance to an ecosystem process, the risk of changing that process given a loss of diversity is very high. If that species is widespread and disperses and colonizes easily, however, then the risk of actually losing it may be low. The most sensitive processes may be those controlled by highly specific interactions that are themselves sensitive to disturbance.

Nutrient-based mutualisms, especially those of mycorrhizas and nitrogen-fixers, are susceptible to eutrophication, acid precipitation and nutrient deposition, with major implications for forest health (Perry *et al.* 1989; Arnolds 1991; Vitousek 1994). Lichenized fungi are sensitive to a variety of chemical stresses (Galloway 1992) independent of biome type. These and other listed mutualisms are sensitive to physical disturbance (Pilz and Perry 1984; Perry *et al.* 1987) and to pollutants, such as acid and alkaline deposition (Adamson and Seppelt 1990; Lovett and Kinsman 1990; Richardson 1992), heavy metals (Zabowski *et al.* 1990; Richardson 1992), pesticides and radioisotopes (Haselwanter *et al.* 1988; Wood *et al.* 1990) in any system in which such anthropogenic stresses occur. In many systems (e.g. island and Mediterranean-type systems; D'Antonio and Dudley 1994; see 6.1.8), exotic species are frequently a problem, and these systems may suffer from addition of N-fixing species (e.g. Vitousek and Walker 1989; Table 6.2-4).

The zooxanthellae mutualists in corals and other marine organisms are sensitive to both natural and anthropogenic disturbances, including storm waves, freshwater pulses from flooding, nutrient loading, sedimentation and over-fishing (Holthus *et al.* 1989; Smith and Buddemeier 1992; Dollar and Tribble 1993; Richmond 1993; Hughes 1994). An important difference between these categories may be that many natural disturbances are episodic and allow recolonization, whereas many human disturbances are chronic and, while perhaps initially more subtle, can result

in long-term changes in viability of the mutualism and the health of the reef (Dollar and Tribble 1993; Hughes 1994; Richmond 1993). The role played by the zooxanthellae in ecosystem nutrient cycling and productivity is relatively well characterized compared to our understanding of how different microbial mutualists affect these processes (Cook and D'Elia 1987; Muscatine and Weis 1992; Falkowski *et al.* 1993). Indeed, it has only recently been discovered that the genetic diversity of algal symbionts, mostly classified within the genus *Symbiodinium*, is equivalent to the diversity between different orders of other microbes (Rowan and Powers 1991, 1992).

Arthropod gut microbiotas, while potentially sensitive due to the restricted number of microbes involved, may be less vulnerable because of lower degrees of host specificity (Martin 1991) than more closely allied mutualisms, such as the fungi of gall midges (Bisset and Borkent 1988) and algae in lichen thalli (Honegger 1992). This may be true in the case of trees able to form ectomycorrhizas with more than a single fungus, though variable environmental conditions and successional relationships could make this diversity important (Perry *et al.* 1989). Mycophagy is widespread in insects but the degree of specificity is frequently unclear (Hammond and Lawrence 1989). Disruption of a microorganism–arthropod mutualism or the sole food source of a fungus-feeding insect would be of particular significance if the arthropod was, for example, the pollinator of a predominant tree, i.e. held a keystone role.

Sensitive pathogenic interactions may be positive (e.g. biocontrol agents; Batra 1982) or negative (e.g. crop pathogens) from a human perspective, with exotic species introductions generally having the greatest visible impact (Dobson and Crawley 1994; Castello *et al.* 1995). Extreme cases can include destruction of dominant native trees by pathogens, with subsequent losses in macro-, meso- and microbiota (Podger and Brown 1989; Wills 1992). In agroecosystems, the genetic simplification of crop plants, rather than loss of microbial diversity itself, can result in adverse microbial outbreaks (Vanderplank 1982; Leonard and Fry 1989). Pathogenic interactions in natural communities may be equally important in determining ecosystem structure and functioning, but are often overlooked because of their subtlety and are much less extensively researched (Burdon and Leather 1990; Burdon 1993; Dobson and Crawley 1994).

6.2.7.3.2 Trace gas production. Microbial trace gas production can be sensitive to species interactions and is particularly important regionally and globally when land-use changes result in changes in rates of release to the atmosphere (Table 6.2-4). The oceanic production of dimethylsulphide (DMS) from relatively few species of phytoplankton plays an important role in atmospheric dynamics as the dominant natural source of sulphate

aerosols (6.2.4). Zooplankton grazing can dramatically increase rates of DMS release (Dacey and Wakeham 1986; Turner *et al.* 1988). The broad distribution of the species involved (Andreae and Jaeschke 1992), however, leads to controversy over whether or not disruption of this process due to species loss is likely in practice (6.2.4). Coastal systems have higher flux rates than pelagic systems and often suffer more intense disturbance from humans, both directly and indirectly through land-use transformations in adjacent terrestrial systems. While they have potential for greater changes in sulphur gas fluxes because of this, the relatively small area of these regions may make the inputs minor on a global scale (6.1.9; but see also 6.2.4).

Land-use transformations leading to increased methane release, such as livestock grazing and rice paddy management, are already responsible for part of the change in Earth's radiative balance (Watson *et al.* 1990). Methane production in temperate and tropical grasslands and agroecosystems is affected by management practices, while climate warming may affect methane production in saturated areas, particularly in northern ecosystems (Table 6.2-4). Changes in methane flux are due to impacts both on the microbial environment (e.g. inducing anoxic conditions necessary for the methanogen functional group, or increasing temperature) and on microbial interactions (e.g. by the bypassing, via plant aerenchyma, of diffusional and microbial (methane oxidizers) boundaries which normally impede transfer of methane to the atmosphere (see 6.2.4). While changes become globally significant only when extended over large areas, the extent to which landscape diversity *per se* contributes has not yet been fully explored.

6.2.7.3.3 Carbon and nutrient cycling. While microbial functional diversity is clearly important in the major nutrient and carbon transformations, the risk from biodiversity loss is scored as 'low' because many micro-organisms appear to be able to undertake these functions (Table 6.2-4). Successional relationships may, however, decrease some of the apparent redundancy. The extent to which this within-group diversity results in process heterogeneity (Schimel 1994) and/or the buffering of systems against changing environmental conditions or species loss, has yet to be determined for most of the processes involved in both terrestrial and aquatic systems. While nitrification is particularly susceptible to pH (Meyer 1993) and may be affected in certain areas by acid deposition, does this mean that the limits of a functional group have been exceeded or merely that pH exerts a direct control on the process? Changes in plant species composition, and thus litter quality, may occur in many biomes for a variety of reasons (e.g. climate change in Arctic, alpine and boreal systems: 6.1.1, 6.1.6; increased disturbance and therefore prevalence of more secondary successional species in tropical forests: 6.1.2; management regimes in grasslands: 6.1.7). This may change microbial

communities (Garland and Mills 1991; Zak *et al.* 1994), but it will probably not interrupt carbon and nutrient cycling. Extreme environments in which a minimal number of species fulfils each functional role could prove to be an important exception (e.g. Friedman *et al.* 1988; Table 6.2-4).

In one subcategory of carbon cycling — the microbial decomposition of hazardous wastes — microbial diversity is clearly important in dealing with the myriad toxic contaminants we have put into our natural and managed ecosystems (Aelion and Bradley 1991). Furthermore, diversity within communities, through co-metabolism, gene transfer via plasmids, provision of necessary co-factors and other mechanisms, is frequently necessary to degrade recalcitrant compounds (Weightman and Slater 1988). We do not know of threats to this diversity other than the inputs of xenobiotics themselves, which is happening in all biomes (Table 6.2-4). Community interactions such as those just listed may be important in other close microbial associations such as biofilms and microbial mats, but their potential for disruption, and the ecosystem consequences thereof, remain largely unexplored. The intentional release of genetically engineered micro-organisms poses yet another set of questions about the potential ecosystem-level effects of microbial diversity (Smit *et al.* 1992). See Section 10 for a further discussion of many of these issues.

In aquatic systems, microbes form the base of the food web leading to macrofauna. As previously described, microbial loops offer alternative pathways for primary production and nutrient transformations. In this case, trophic diversity within size-based functional groups (both plankton and metazoans) influences pathways of nutrient regeneration and carbon/energy flow, and has implications for fisheries (Pomeroy 1991; O'Brien *et al.* 1992; Steinberg and Geller 1993). Loss of phytoplankton productivity itself may not be currently under major threat from changes in microbial diversity (the major exception being cases of severe pollution which push environmental conditions beyond the bounds of most primary producers). However, both directly and through species interactions, nutrient loading can alter pathways of carbon cycling (e.g. Peterson *et al.* 1985, 1993), can result in plankton blooms leading to anoxia in extreme cases, and can also result in changes in species composition leading to outbreaks of noxious species such as red tide (6.1.9). Coastal and freshwater systems are particularly susceptible to such disturbances due to their proximity to terrestrial sediment, toxics and nutrient sources.

6.2.7.4 Conclusions

Despite our relative lack of knowledge in the face of the staggering diversity of microbes, we do know something about the importance of many microbial functional groups. We can begin to look at how microbial diversity affects

Table 6.2-4: Microbially mediated ecosystem processes and their sensitivity to the loss of biodiversity. See text for references.

Sensitivity ¹	Ecosystem functions	Interface ² and biome ³	Organisms	Ecosystem processes affected	Ecosystem processes involved	Human threats
High	Biotic interactions					
	1. Mutualisms	1,2,3 TeF, TrF, TrS	Mycorrhizas	Nutrient cycling, primary production physical disturbance	Nutrient and water uptake	Eutrophication, acid deposition,
		2,3,4 CoR, CoS, L&R, Med, TeF	N-fixers (nodule formers, cyanobacteria)	Nutrient cycling primary production	N-fixation	Eutrophication, physical disturbance, species introductions
		2,3,4 TeF, ArL	Lichens	Primary colonization, biogeochemical weathering	Photosynthesis, N-fixation	Acid deposition
		2,3,4 ArL	Cryptogamic crusts	Primary production, soil stabilization	N-fixation	Acid deposition, physical disturbances
		4 CoR	Corals	Primary and secondary production	Photosynthesis	Eutrophication, physical disturbances, sedimentation, over-fishing
		2 all	Arthropods/bacteria	Decomposition	Cellulose digestion	No known immediate threats
	2. Pathogens	2,3,4 AgE	Myriad	Primary and secondary production	Natural biocontrol and population control	Genetic simplification species introductions species losses
High	Trace gas production	1,3 AA, AgE, BoF, TeF, TeG, TrS	Methanogens/ methanotrophs	Radiative balance	Methane production and consumption	Land-use transformations e.g. grazing, rice paddies, N fertilization

High	Xenobiotic degradation	1,3 all	Myriad	Carbon cycling	Metabolism of recalcitrant/toxic substrates	Xenobiotics may both threaten diversity and select for novel organisms
Low/High	C and nutrient cycling	1,2,3,4,5	Microbes in extreme environments	Primary production, nutrient cycling, decomposition, soil structure		Physical and chemical disturbance – extent not known
Low/High	C and nutrient cycling	1,2,4 CoS, CoR, L&R, TrE	Phytoplankton	Primary production, secondary production, decomposition	Primary production	Severe pollution, eutrophication
Low	All other	1,2,3,4,5 AA, BoF, TeF, TeG, TrE, TrF	Myriad	Nutrient cycling, carbon cycling, soil formation	Decomposition, mineralization, nitrification, denitrification, immobilization primary production, ecosystem respiration. Soil organic matter synthesis and breakdown, etc.	Changes in plant species composition

-
1. 'Sensitivity' refers to potential for change/disruption of ecosystem processes due to change/loss of biodiversity; High = dependence on either a few species or very specific species interactions, or particularly subject to disruption. Low/high = in general assumed not to be sensitive but may be highly vulnerable in extreme environments or near-shore aquatic systems; Low = due to the lack of adequate information, generally assumed not to be sensitive.
 2. Interfaces: 1 = atmosphere/biotic; 2 = biotic/biotic; 3 = biotic/soil; 4 = biotic/hydrologic; 5 = soil/hydrologic.
 3. Biomes: AA = Arctic and Alpine; AgE = Agroecosystems; ArL = Arid Lands; BoF = Boreal Forests; CoR = Coral Reefs; CoS = Coastal systems; L&R = Lakes and Rivers; Med = Mediterranean-type; OpO = Open Oceans; TeF = Temperate Forests; TeG = Temperate Grasslands; TrE = Tropical Estuaries; TrF = Tropical Forests; TrS = Tropical Savannahs.

ecosystem-level processes, and how this may be threatened by human impacts, by using the criteria of specificity of interactions, sensitivity to disturbance, and diversity within functional groups. Some or all of the assumptions underlying these criteria may need further testing.

For carbon and nutrient transformations, the importance of microbial functional diversity is well known. However, these processes do not seem to be immediately threatened unless anthropogenic changes cross process-level thresholds by pushing the range of environmental conditions beyond either the ability of particularly sensitive and specific micro-organisms to operate (e.g. pH with nitrifiers; Meyer 1993) or the abilities of the microbial assemblages in that group to respond. This assumes that the species diversity within most functional groups related to carbon and nutrient cycling substantially buffers processes in changing conditions (Hobbie and Ford 1993). For this reason, we conjecture that microbial communities in extreme environments, in which a restricted number of species carry out each process step, are particularly susceptible to these changes. The role of diversity within functional groups, however, has barely been explored, not only for microbes but for most organisms and processes.

Biotic interactions, both mutualistic and pathogenic, belong to another category of microbial diversity that may substantially affect ecosystem-level processes and which is probably the one currently most threatened by anthropogenic activities. The sensitivity of mutualisms to disruption may be a function of both their specificity and the number of different species involved (again, within-functional group diversity), though ecosystem level impacts would be expected only where the interactions are widespread or in some sense 'keystone' in nature. Pathogenic interactions have the most dramatic effects on natural systems when either the host or the pathogen (or both) are introduced (Dobson and Crawley 1994).

For diverse functional groups, we need to look more closely at how changes in diversity affect the boundaries of processes (i.e. determine thresholds of functional change) as well as how such changes modulate the rates of those processes. For very specific biotic interactions or important element transfers carried out by few species, we need more information on their susceptibility to both physical or chemical disturbance. As McNaughton (1988) has previously observed, microcosm experiments which manipulate both species composition and diversity (e.g. Hairston *et al.* 1968) could provide useful insights both for microbial communities and for general principles on how diversity affects ecosystem properties.

6.2.8 Agroecosystems

6.2.8.1 Introduction

Agroecosystems are ecosystems in which people have deliberately selected crop plants and livestock animals to replace the natural flora and fauna. These artificial systems vary enormously in the intensity of human intervention (Harwood 1979), from those with only low-intensity management (e.g. shifting cultivation, home gardens, nomadic pastoralism, traditional compound farms, rotational fallows and savannah mixed farming) to those of middle-intensity management (including multiple cropping, horticulture, improved pasture mixed farming and alley farming), and high-intensity management (intensive cereal cropping and crop rotations, orchards and plantations, and intensive livestock raising). Intensive cropping systems are often monospecific and usually composed of genetically uniform plant stands. Functioning in agroecosystems is determined by the production goals of the farmer which include economic, cultural and often aesthetic values as well as those of biological production. Dependent on the circumstances of the farmer, preference may be given to short-term maximization of specialized productivity or to the diversity, persistence and stability of production. These factors influence the way in which biodiversity is managed.

6.2.8.2 Impact of agricultural intensification on relevant biodiversity components

There is no simple quantitative index of agricultural intensification but increasing human intervention results in a deliberate reduction of the diversity of plant and vertebrate animal species. Continuing harvesting and the practices of plant, soil and pest management lower the diversity of associated plants, invertebrates and microbes (Swift *et al.* 1995). Many of the changes in ecosystem diversity and complexity associated with intensification

affect a variety of ecosystem functions. Modern intensive agriculture utilizes a narrow range of crop species and genetic varieties which have been bred for high yield, including response to inorganic fertilizers and resistance to selected pests and diseases (Vanderplank 1984; Fageria 1992). Less intensive systems commonly incorporate a wider range of species and genotypes which serve a variety of production goals and/or are used for differential exploitation of microhabitats, and for their resistance to diseases and pests (Ramakrishnan 1992). Decreased plant diversity often reduces the overall biomass and almost invariably the structural complexity of the ecosystem. Multi-strata high-biomass vegetation is replaced by single-canopy monocrops often incorporating varieties with a reduced proportion of non-grain biomass. Complex horizontal patterns of intercropping are succeeded by monocultural row cropping (Wolman and Fournier 1987). Decreases in the diversity of plant species lead to increased pest and disease problems. This is accompanied by a drop in the diversity of invertebrate consumers, predators and parasites (Altieri and Liebmann 1986) a feature further exacerbated by the use of pesticides. Substitution of annual for perennial vegetation reduces the extent of soil cover and produces periods when the soil is left bare. These selective influences produce decreases in the quantity and diversity of organic matter inputs and residues, the mineral nutrient content of which may be substituted by inorganic fertilizers. Decreases in organic inputs and removal or burning of residues also reduce soil cover. Above-ground changes are reflected below ground by decreased biomass, diversity and complexity of rooting systems, and particularly the absence of deep rooting which comes from exclusion of trees from the systems (Persson and McMichael 1991).

At the landscape scale, intensification of agriculture commonly includes an increase in the size of fields and progressive specialization in production goals leading to homogenization of the landscape both within farms and across substantial areas or even regions (Wolman and Fournier 1987). This entails a move away from farming systems with a diversity of different production systems, e.g. home gardens (gardens for fruit, vegetables, spices and medicines), a variety of specialized or species-diverse crop fields, including systems related to specific micro-environments (e.g. wetlands used for rice cultivation) and associated livestock production areas (including aquaculture in wetlands) (Okigbo and Greenland 1976). This homogenization reduces the complexity of the interface between units on the landscape and leads to reduced biological migration, habitat diversity (particularly of ecotones) and disruption of nutrient flows.

6.2.8.3 Ecosystem consequences of impacts

6.2.8.3.1 Productivity capacity, biomass and decomposition. The utilization of high-yielding varieties

has enabled farmers to exploit the full range of yield potential for many crops in many environments (Fageria 1992). Monocultures also can increase the efficiency of management by facilitating harvesting and simplifying marketing of the product. The narrowing of the genetic base for host resistance (particularly by dependence on a few 'major genes') produces an increased risk of yield loss through epidemic outbreaks in contrast to the 'chronic' status of disease in systems with a range of genotypes including those incorporating 'tolerance' characteristics and multiple-gene resistance (Vanderplank 1984). In some environments intercrops, tree-crop combinations and rotations show significant yield advantages over monocrops (Francis 1989; Vandermeer 1989). A component of this yield advantage is attributed to reduced pest and weed infestation due to enhanced natural biological control by natural predators (Altieri 1987). Reduced amounts and diversity of organic residues result in a reduced range of decomposition rates in intensive systems (Tian *et al.* 1992).

6.2.8.3.2 Soil structure and nutrients. The practices employed in clearing land for cultivation, subsequent tillage, the lowered diversity and complexity of rooting systems, and the decreased biomass and diversity of organic inputs to the soil, all act to reduce the diversity of soil organisms (Hendrix *et al.* 1990; Swift and Anderson 1992). These changes in below-ground diversity may extend to the elimination of keystone species or even entire functional groups. Some of the groups are general in distribution e.g. nitrogen-fixing bacteria, mycorrhizal fungi and predators of soil-borne pests, whilst others such as earthworms and termites are more environmentally restricted in their distribution. Clearing of vegetation and subsequent tillage leads to a decline in soil organic matter and the consequent loss of associated properties of nutrient storage, cation exchange and moisture-holding capacities (Greenland 1981). Decline in SOM is most rapid in tropical environments and also has more serious effects in the highly weathered soils of these areas which have low activity clays and thus little capacity to compensate for loss of the functions associated with SOM. Increased use of inorganic N, together with enhanced decomposition and nitrification rates, results in increased loss of N as NO_3 leachate or by volatilization or denitrification and soil acidification (Lowrance *et al.* 1983). The availability of high levels of inorganic N may also increase the nitrate to protein ratio in above-ground vegetation leading to enhanced susceptibility to pests and pathogens (Altieri 1987). Reduced vegetation and litter cover increases the risk of erosion (Boarden *et al.* 1990) and recorded rates of erosion in many environments now indicate losses of topsoil much in excess of the rates of renewal (Pimentel 1993). Increased biomass of livestock can result in soil compaction and changes in soil water regimes (Bochet 1983).

6.2.8.3.3 Water distribution, balance and quality. Decreased soil cover from canopy and litter together with a lack of contour barriers and deep-rooting plants results in decreased infiltration and increased water runoff (Hamilton and King 1983). Increased use of inorganic fertilizers across the landscape, associated with decreased capacity of the soil community to immobilize nutrients, and the absence of deep-rooting systems, leads to eutrophication of ground water (Lowrance *et al.* 1983). The same effects may be felt from disposal of high-N manures from intensive livestock production.

6.2.8.3.4 Atmospheric properties. Enlargement of the net area of agricultural land gives rise to increased CO_2 , CH_4 and NO_2 when the primary productivity of the subsequent cropping system is lower than that of the vegetation it replaces. This difference is most marked in agriculture based on annual cropping, but it may be significant even in fallow rotation systems where the biomass and persistence of vegetation is low due to shortening of the fallow period. Similarly continued burning of residues may or may not lead to net emission balances dependent on whether or not this is balanced by subsequent fixation of C and N. Additional changes in carbon equilibrium come from oxidation of soil organic matter in the absence of a sufficient input of organic matter to balance this loss (Bouwman and Sombroek 1990). Agroecosystems with higher plant biomass (e.g. those incorporating trees or with fallow biomass periods in the cropping cycle) can help to compensate for these imbalances. Clearing of natural vegetation, and drainage of wetlands for cultivation, may be a major source of CO_2 emission from oxidation of the large stocks of organic matter. Methane is generated from anaerobic decomposition in wetlands, and increases in the area of permanently or near-permanently flooded rice cultivation are thought to account for a significant proportion of the increase in net CH_4 emission (Schutz *et al.* 1990). Intermittently wet and dry systems produce less CH_4 but more CO_2 . Methane is also produced by anaerobic digestion in animal guts and increased specialization of ruminant production has contributed significantly to global CH_4 emission (Schutz *et al.* 1990). Increases in N_2O emissions have been linked to the stimulation of denitrification following intensified use of inorganic-N fertilizers (Bouwman and Sombroek 1990) and from expansion of the area of flooded cultivation.

6.2.8.3.5 Landscape and waterscape structure. Complex agroecosystems have substantial linkages between production units in the form of natural migrations of biota (e.g. of pest predators from fallow vegetation refuges to crop areas; livestock feeding in crop fields in the dry season) or of materials (e.g. transfer of nutrients and organic matter from livestock pens as

fertilizer to arable fields; cutting of fodder in fallow areas; Swift *et al.* 1989). Specialization in production and simplification of the landscape have increased the economic efficiency of many intensive agricultural systems resulting in highly productive and profitable agribusinesses. Homogenization of farming areas leads to changes in hydrological patterns such as increased and less stable flows of water across the landscape, particularly above ground (Hamilton and King 1983; Lowrance *et al.* 1983). This, together with a lack of windbreaks, increases the rates of erosion and disruption of nutrient cycles. These effects can be reduced by increased vegetational cover and use of appropriate soil conservation methods which also lead to improved diversity. When these factors are included in the economic cost of modern agriculture the economic and energetic efficiency advantage over more diverse systems or landscapes is substantially reduced (Pimentel and Pimentel 1979). Agricultural homogenization has an impact far beyond the field (ecosystem) scale by removing refuges and microhabitats for the migration of biota, and by creating a more exposed and harsher environment.

6.2.8.3.6 Biotic linkages and species interactions. The biotic and structural simplification that result from agricultural intensification necessarily reduces the variety of biotic linkages in the system, including those below ground (Edwards *et al.* 1988). Intensive agroecosystems are as a consequence unstable in many respects (e.g. open nutrient cycles, reduced capacity for biological pest control, greater susceptibility to climatic change, Edwards *et al.* 1990). These biological controls are substituted by industrially based regulators such as fertilizers, pesticides and mechanical management. The alternative to substitution is the redesign of agroecosystems to include greater biological diversity and complexity. Such systems (e.g. modern multiple cropping and agroforestry) have enhanced capacities for self-regulation of pests and diseases, tighter nutrient cycles and higher energetic efficiency (Altieri 1987; Swift *et al.* 1995).

6.2.8.3.7 Microbial activities. Agricultural intensification leads to changes in diversity, composition and abundance in all studied groups of micro-organisms. Effects on functioning are variable. The range of pathogenic interventions may be narrowed but the intensity may be increased; symbiotic functioning such as N-fixation and mycorrhiza may be diminished by the use of inorganic N and P fertilizers (eg. Ladha *et al.* 1992; Read *et al.* 1992) but nitrification may be enhanced. On the other hand, although total microbial biomass may decrease there is little evidence that general functioning such as decomposition or SOM dynamics are affected (Swift *et al.* 1995).

6.3 Conclusions

6.3.1 Background

Understanding the role of biodiversity's elements in the functioning of ecosystems is a relatively new field of research endeavour. This science is crucial in its own right for learning about the evolution of biotic interactions, the structural and functional properties of ecosystems, and the degree of sensitivity of these properties to changes in underlying diversity. Understanding the functional role of biodiversity is also important in management applications. Valuable scientific principles and guidelines for making ecosystem management decisions are beginning to emerge in spite of the field's youth and the relatively small number of experimental studies from which we can draw. We can

expect much more to follow in the near future as these research areas gather momentum.

6.3.2 The importance of ecosystem approach

The ecosystem integrates both the physical and the biological environment, and thus changes in any of the elements of the ecosystem affect the quantity and quality of its functioning. These changes in functioning may themselves then affect the biological composition of the ecosystem, its physical characteristics, and its dynamics. From a very practical standpoint, it is the ecosystem, and the array of ecosystems over entire landscapes and regions, that provides a broad diversity of goods and services to human society. The ecosystem is the level of ecological organization that most closely corresponds to the primary targets of most management decisions. Therefore, understanding the functional consequences of changes in the underlying biodiversity assumes tremendous importance for managers and scientists alike.

6.3.3 Ecological goods and services

Of particular importance in understanding the role of changes in biodiversity in ecosystem functioning is the concept of ecological goods and services. Ecosystems obviously provide marketable commodities, e.g. food from fisheries and agroecosystems and timber from forests (Box 6.3-1). Ecosystems also provide a wealth of products from which marketable goods are made, e.g. taxol from the North American yew (*Taxus brevifolia*), or from which they can ultimately be synthesized, such as the precursor to taxol found in the commonly occurring European Yew (*Taxus baccata*) or the original sources of aspirin and

Box 6.3-1: Biodiversity's influence on yield.

Yield is one of the most important parameters to understand and manage sustainably in managed ecological systems. In agricultural systems, genetic diversity is very important for determining yield (Section 5.2.1). Although the highest known yields in terrestrial systems occur in species monocultures (6.2.1), substantial amounts of energy, fertilizer and pesticide are required to maintain these levels, and their long-term sustainability is difficult to ascertain. Moderate yields can be achieved without energy subsidies in managed mixed crops (6.2.8), suggesting that increased diversity at the species level can reduce the overall subsidies needed to maintain adequate, although not maximum, yields. Management that decreases animal diversity in pastures is correlated with increased yield of animal products (6.1.7). Loss of coastal habitat diversity can lead to lessening of production in unmanaged fisheries (6.1.9).

digitalis. Ecosystems further provide services for which there are obvious economic returns: ecotourism, whose popularity is growing world-wide, is one example, but the same principles hold for sport fishing and hunting, where the economic activities range from the purchase of licences to expenditures for travel and lodging.

Ecosystems also provide services that are more difficult to measure in economic terms, but which are nevertheless fundamentally important to our quality of life. For example, wetlands provide substantial capabilities to assimilate wastes and to purify the water that flows through them; microbial diversity can be important for the degradation of hazardous wastes; adequate functioning of the soil microbiota is partially responsible for the maintenance of soil fertility, while the contribution of intact forests in controlling soil erosion, particularly in mountainous regions, is well known. Although diminutions in these services can be shown to have social and economic costs, markets do not capture their full worth. They have thus been labelled ‘free’ services (Box 6.3-2). Our understanding of ecosystem functioning must be improved so as to enable society to maintain these ‘free’ services, as well as providing marketable goods and services. Building this understanding is an increasing challenge for managers and scientists.

6.3.4 Drivers of change

Human activities are now the dominant force in causing the alteration, redistribution and loss of biodiversity. The rate at which humans are altering the environment, the extent of that alteration, and the consequences of these changes for biological diversity are unprecedented in human history, and are now beginning to pose substantial threats to economic and cultural aspects of many societies. Depending on the circumstances, human activities may increase, maintain or diminish the diversity of species, genes or ecological communities in a given region and at a given time, but the general trend is an increasing loss of biodiversity at the global scale. Some of these changes, such as the erosion of genetic variability and the extinction of species, are truly irreversible: others are not, but the challenge of managing natural resources while maintaining adequate levels of biodiversity has increased markedly. Moreover, pressures on biological diversity are likely to increase still further as a consequence of human-induced climate change.

6.3.5 Factors affecting the functional sensitivities of ecosystems

Reductions in species diversity can reduce the ability of ecosystems either to resist stress from environmental factors or to recover from disturbance. For example, coral reefs, mangroves and kelp forests can buffer adjacent terrestrial systems from ocean waves, and thus the presence of coastal landscape diversity can mitigate the effects of

Box 6.3-2: Water quality and flood control: provision of ‘free’ services by ecosystems.

Biodiversity at both landscape level and species level influences water quality and quantity. For example, conversion of vegetation within a watershed from forest or shrubland to grassland increases stream-flow out of the watershed. Loss of the woody overstorey in riparian systems greatly increases water temperature, and reductions in the diversity and productivity of the herbaceous layer increase the velocity and erosive capacity of the stream-flow (6.1.7). Thus, landscape-level conversions, particularly those involving hydrological changes associated with clearing forested watersheds, can increase flows and the variance of flows, making flood control more difficult and expensive.

In aquatic ecosystems, even the addition of a single species can greatly affect water quality. For example, the accidental introduction of the zebra mussel into the Great Lakes greatly increased water clarity due to its tremendous filtering capacity and rapid population growth (Ludyanski *et al.* 1993). This increase in clarity, unfortunately, comes at the expense of many natural plankton communities, and thus affects fish populations.

storms that would otherwise produce substantial erosion (6.1.9; 6.1.10; 6.1.11). Experimental studies have shown that species-rich temperate grasslands exhibit smaller changes in plant biomass after drought than less rich areas (6.1.7). The existence of relatively undisturbed communities within a mosaic of different land uses can serve as sources of propagules, seeds and dispersing animals to recolonize areas that have been adversely affected by other stresses (6.1.1).

The sensitivity of ecosystem functioning to changes in biodiversity appears to be influenced in part by the number of species that contribute to processes in similar ways (6.2.2). For example, the functional consequences of species losses should be greatest for those systems that have few species – such as boreal forests, deserts and islands, because there are few species that can substitute for the deleted taxa, and thus the chance of adversely affecting an ecosystem process from even a single deletion is high (6.1.4; 6.1.6; 6.2.6; 6.2.7). For example, emissions of methane, nitrous oxide, dimethyl sulphide and volatile organic chemicals, each seem to depend on a limited number of taxonomic groups with functionally similar properties. It is not understood why this is the case, but it seems reasonable to presume that the marginal effect of losing any one of them would be high.

Conversely, ecosystems or processes with many functionally similar species should be better protected from such disruptions in the long term, because there are more species that respond differently to environmental stress. For example, a wide variety of organisms comprise the functional group of primary producers, and there is no good evidence that primary productivity in ecosystems depends strongly on the number of species, within reasonable limits (Box 6.3.3).

On short time scales, some degree of substitutability can be documented in particular cases (6.1.1). In a temperate grassland system, dominant species fully compensated for the removal of subordinate species, while the subordinate species only partially compensated for the removal of dominant species (6.1.7). Substitutability has some limitations, however. At the genetic level, populations may not be completely substitutable because of local adaptations. Thus, even for small areas, when a longer timescale is considered, our best understanding is that functional substitutability among species is limited, and it is unwise to assume that species are functionally redundant.

Ecosystems can vary tremendously in the number of functionally similar species they contain, and there is no consensus on what determines the number of functionally similar species in particular biomes. For example, marine ecosystems (open ocean, near coastal, estuarine) tend to have greater phyletic diversity among functionally similar species than do terrestrial ecosystems, due at least in part to their greater overall phyletic richness. Many tropical terrestrial ecosystems have large numbers of apparently

functionally similar species, especially when compared to their temperate analogues. Even within a climatic zone, historical factors can result in substantial variation in the number of functionally similar species, as is seen in the wide variation in numbers of flowering plant species in different zones of temperate deciduous forest and different Mediterranean ecosystems.

Each individual species may play many different functional roles, which are rarely fully understood. It is possible for an organism to have a suite of biological traits that confer on it a dynamic importance out of proportion to its abundance, i.e. it plays a keystone role in organizing structure and processes throughout an ecosystem. The effects of moose and reindeer on boreal and Arctic ecosystems; sea otters in northern California kelp forests; many parasitoids and parasites in biological control programmes; and the major grazers on grassland ecosystems, all provide well-documented examples. The full influence of such species is generally only seen and understood when it has been lost from the system. Our ability to predict *a priori* which species will have such effects is very poor, and they may occur in either species-poor or species-rich systems.

When changes in ecosystem composition and functioning do occur, they are often gradual. However, some systems, especially islands, lakes and agroecosystems, exhibit dynamic thresholds in their response to a major stress or disturbance that affects diversity. Others seem to be susceptible to chronic stress, and these tend to have very few species with functional similarities: e.g. boreal, Arctic and alpine systems.

Box 6.3-3: How does biodiversity influence productivity?

The relationship between biodiversity and primary productivity needs to be considered over both short and long time scales. On relatively short time scales and small spatial scales, the most important issue is whether reductions in species diversity will adversely impact productivity. Over longer time scales, the role of diversity in the maintenance of productivity in systems undergoing a variety of stresses becomes paramount.

In most biomes, primary productivity appears to be only weakly related to the number of plant species, as it usually peaks at relatively low species-richness levels (6.2.1; 6.1.2; 6.1.7). Diversity may play a role in the maintenance of productivity in the face of natural and human-induced change (e.g. disturbance, drought, climate change, toxins) (see 6.2.1; 6.1.2), and changes in landscape configuration can have large and long-lasting effects on regional productivity (e.g. banded vegetation systems, 6.2.5).

6.3.6 Invasions, introductions and species losses

International travel and trade, in addition to climatic variation, provide opportunities for the deliberate introduction or accidental invasion of species into new ecosystems. When a species enters an ecosystem in which it previously did not occur, it can either adversely disrupt ecosystem processes or have positive effects — such as providing biocontrol of pests or pathogens in agroecosystems. Microbial species introductions, particularly of plant pathogens, have had a large effect on ecosystem composition in both natural and managed systems, but these effects do not always have large observable effects on ecosystem processes (6.2.7). For example, the loss of chestnut from eastern deciduous forests in North America, due to the introduction of chestnut blight from Europe, was both rapid and dramatic, but there have been no discernible consequences for ecosystem functioning as other tree species seem to have fulfilled its original functional roles. On the other hand, introductions of new capabilities such as nitrogen fixation into ecosystems whose component species previously did not have this ability, typically have dramatic changes in

both composition and ecosystem functioning. The introduction of nitrogen-fixing trees into sites in Hawaii has led to a complete restructuring of the plant communities, with consequent changes in nutrient supply, fire frequency and water availability. Biotically impoverished systems whose major species have only limited genetic diversity, such as many production agroecosystems, are often very susceptible to the effects of introductions and invasions (5.2.1; 6.2.1; 6.2.6), with the introduction of pathogens being of primary concern.

Islands and ecosystems with relatively few component species, such as boreal forests, seem to be more susceptible to species invasions than species-rich biomes such as tropical forests, so it would be expected that invasion of species leading to disruption of ecosystem processes is more likely to occur in the former than in the latter (6.2.6). Freshwater ecosystems in all climatic zones also seem to be especially sensitive to invasions and introductions (6.1.13). In general, areas of ecosystems that have been subjected to disturbance or stress from other environmental factors, such as fire, drought, overgrazing or extensive clearing, can provide open habitat and resources that allow invaders to become established. Whether or not introduced species will spread from their original entrance depends on the particulars of their biology, and the biology of the native species they encounter. Apart from these generalizations, there is very little ability to predict *a priori* the effects of accidental or deliberate introductions, suggesting that considerable prudence be exercised.

6.3.7 Transformation and fragmentation of populations and ecosystems

The net effect of human activities may possibly be an increase in the overall diversity of ecosystem types around the world, some of which are extremely important to societal well-being. Human activities are, for example, directly responsible for creating agroecosystems. However, these increases in the diversity of ecosystem types have come at the expense of impoverishment of a great number of natural communities, and the reduction of at least some ecosystem services.

Some fragmentation of existing ecological communities is inevitable, except in areas that have been specifically protected. In nearly all cases, the fragmentation of existing communities reduces the diversity of native species in their natural habitats. Human impacts, in particular habitat loss, fragmentation and over-exploitation, tend to reduce severely the size of many biological populations, and this increases the risk that a population will be lost, ultimately leading to species' extinction. Even when the species does not become extinct, its loss from a local region or a major reduction in its population can have significant consequences for human livelihoods and ecological services. The species most likely to be lost are large

predators and other species with large body sizes and area requirements. Also likely to be lost are species with less ability to disperse among and colonize habitat patches. Species likely to survive fragmentation will be those best adapted to patchy and frequently disturbed environments, especially early successional and easily dispersed species. Fragmentation is thus expected to result in ecosystems dominated by such 'weedy' species. Such systems have characteristically higher losses of nutrients, nitrogen and carbon; higher litter quality and therefore faster decomposition rates; simpler spatial structure; and less overall protection from herbivory than the original communities that preceded them.

No biome is functionally resistant to landscape-scale changes in diversity, particularly those changes due to anthropogenic alterations. The large-scale conversion of ecosystems in landscapes tends to have long-lasting effects on system processes independently of whether the particular ecosystems were originally of high or low diversity. For example, the large-scale transformation of forested ecosystems to pastureland, grasslands and agriculture has been an important contributor to the increase in atmospheric carbon dioxide over the last several hundred years. The first phase of this transformation occurred in the developed countries of the Northern Hemisphere, but in recent decades tropical conversion of forested ecosystems to grassland has become the main contributor. During the 1980s, conversion of tropical forest to grassland contributed approximately 1.6 gigatons of carbon per year to the atmosphere, in addition to the 5.5 gigatons of carbon per year released by fossil fuel combustion. This was slightly offset by regrowth of temperate and boreal forests, which sequestered about 0.5 gigatons per year during the same time period. Improved management of forested ecosystems and reforestation in both the temperate and tropical regions can continue to sequester carbon from the atmosphere and move it to longer-lived soil pools, thus reducing the rate at which greenhouse gases are added to the atmosphere.

The interactions among different ecosystems determine a landscape's functional sensitivity to changes in diversity. Landscape-scale functions are affected by changes in diversity at lower hierarchical levels either when the changes in diversity affect the strength of the spatial interaction, or when the changes in diversity affect the strength of sources or sinks of the materials being transferred. There are characteristic differences in these aspects of ecosystem 'connectedness': e.g. ocean systems have high connectedness compared to terrestrial systems, therefore changes in one place may ultimately have effects far away. In many terrestrial systems, the connectedness of landscape components is determined by water flow, and thus both topography and vegetation play major roles in determining landscape-level functional responses. However,

even in terrestrial systems, atmospheric or climatic stress or disturbance, or processes that produce feedbacks to the atmosphere, operate through a medium that provides high connectedness. The acidification of soil and surface water in forested landscapes; changes in soil microflora; and loss of nitrogen from previously nitrogen-limited forests as a consequence of acid precipitation in North America and Europe, demonstrate that landscape-level functional changes can occur in terrestrial systems because of atmospheric stress.

Within reasonable bounds, we cannot consider transformations of ecological communities to have only local effects. In marine systems, changes in geographically distant ecosystems may greatly affect one another through, for example, larval transport or the transport of pollutants by currents (6.1.12). Even in terrestrial ecosystems, migratory animals and the atmosphere provide similar linkages between distant ecosystems. Fragmentation of temperate forests in North America can, for example, affect the survivorship of tropical-temperate migratory birds, which are important seed dispersal and biological control agents in neotropical areas. Changes in forested watersheds can have obvious effects on water flow and quality far downstream. Current rates of forest conversion will also reduce potential or actual sustainable economic benefits due to soil and water conservation services, recreation and tourism, and non-timber products.

6.3.8 Goods and services at risk

The transformation, fragmentation and loss of habitats has had many different effects on the provision of ecological goods and services. The massive creation of new agroecosystems has obviously resulted in the ability to increase food production dramatically. At the same time, it has led to the impoverishment of natural communities and can reduce the ability of ecosystems to maintain productivity in the face of environmental fluctuation. Substantial alteration in soil fertility can be driven by changes in plant species composition and microbial functional groups which are required for the cycling of important plant nutrients. The loss of particular plant species and loss of critical communities, such as forested watersheds, can reduce the ability of ecosystems to control soil erosion and retain water. Conversion from forest or shrubland to grassland dramatically increases stream-flow, and if this occurs in the upper reaches of watersheds, can increase the need for additional water control measures through dams. Thus, degradation and conversion of forested watersheds can result in significant economic costs due to increased flooding and sedimentation.

The rapid transformation of forested ecosystems without regard for appropriate management of water resources, has had serious consequences for human health (Box 6.3-4). Deforestation led to major malaria outbreaks in the western Amazon, due to the creation of new habitats for mosquito

Box 6.3-4: How do disruptions in biodiversity influence human health?

Disruptions in biodiversity can affect disease transmission either through their influence on vectors of disease, or more directly on their influence on the disease-causing organisms themselves. Changes in landscape diversity, due to agriculture, have resulted in the spread of human diseases. For example, the introduction of slash-and-burn agriculture into wet tropical Africa resulted in an increase in malaria which in turn increased the occurrence of sickle-cell anaemia (5.2.1). Physically damaged reefs are often invaded by the dinoflagellate *Gambierdiscus toxicus*, which is responsible for ciguatera in humans (6.1.10). Unidentified precursors in the dinoflagellate are transformed into toxins which accumulate in food chains leading to table fish.

Other direct or indirect effects on health can come from biodiversity's influence on particular ecosystem processes. Changes in plant species composition can result in changes in the emissions of volatile organic compounds by plants which can lead, along with industrial pollutants, to increases in tropospheric ozone that can indirectly affect human health (6.2.4). Rooting depth changes as a result of replacing species when forests are converted to agricultural systems. These changes in rooting depth affect the amount of water percolating through the soil and may increase the levels of nitrate in ground water (6.1.4; 6.1.7).

vectors, and also to the increased colonization of the region by susceptible human populations. However, management of vector habitats, when coupled with other public health measures, dramatically reduced the incidence of the same disease in the southern United States.

Increases in the extent and yield of rice agroecosystems have provided food for vast numbers of people. At the same time, the increases in rice cultivation and livestock husbandry have been major contributors to the increased methane concentrations in the atmosphere, and thus to concerns over greenhouse warming. It is likely, although less certain, that increases in the use of nitrogenous fertilizer in the tropics in order to enhance agricultural productivity are also contributing to rising atmospheric concentrations of nitrous oxide, a very powerful greenhouse gas, in the atmosphere (Box 6.3-5).

Transformation of parts of ecosystems that then acquire substantial economic value often requires intensive management in other parts of the ecosystem. Fire control in forest ecosystems provides one example. Fire control in

many forests provides substantial benefits for adjacent property owners, and for hunting and recreation. However, because fire control completely alters the frequency of naturally occurring fires, it also can have the unintended side-effect of contributing to the buildup of fuel, possibly leading to more intense fires which have adverse effects on plant regeneration and wildlife habitat, and threaten human habitation. Prescribed burning can partially mitigate these potential adverse consequences, but can itself be expensive. Fire control thus illustrates the need to balance carefully the costs and benefits of maintaining diversity in ecological communities.

Over-exploitation in extracting materials and goods from converted or degraded ecosystems, such as poorly managed cropping and timber harvesting, while providing food and wood, also tends to disrupt some ecosystem services by decreasing the ability of the ecosystems to retain nutrients, water and topsoil. These effects are due directly to the mechanical effects of extracting the desired materials, along with the longer-term biogeochemical effects of removing carbon, nitrogen and nutrients from the systems. Over the long term, reductions in soil carbon and soil fertility, and increases in overland flow and sedimentation rates, are often the result (Box 6.3-6). Increased fertilizer and pesticide subsidies are then often required to maintain adequate agricultural yields, resulting in increased direct costs.

The introduction of non-native species, and over-exploitation of resources, has been especially problematic in grassland ecosystems. In arid and semi-arid regions, the introduction of cattle, sheep and other non-native grazers, subsequent overgrazing, over-use of fire, and the introduction and spread of alien plant species, can result in desertification because the new species lack the adaptations of the natural communities for using water efficiently in the face of the original herbivores.

6.3.9 Implications

Understanding the functional role of biological diversity is important scientifically, but as our analysis makes clear, it also is important from a managerial and policy perspective. Changes in biodiversity will, to the best of our current knowledge, have important implications for sustainable resource management, and for the continued provision of ecological goods and services. Our analyses suggest that these implications may be particularly important for longer time scales, especially for those ecosystem processes and goods such as primary productivity and crop yields that do not depend strongly on diversity over short time scales. As the need for sustainable management of ecological goods and services increases, the maintenance of these processes becomes more important over long time scales, and the importance of considering biodiversity as a component to be managed also increases. Ecosystems can be managed so as to maintain goods and services that might otherwise be lost, if

Box 6.3-5: How does biodiversity influence atmospheric composition and climate?

The influence of biodiversity on air quality is not generally thought to be strong in comparison with direct anthropogenic effects. However, there is some relationship between the actual composition of ecosystems and landscapes and air quality. Because different plant species emit different volatile organic compounds, species composition can affect the concentration of tropospheric ozone, in conjunction with industrial pollutants (6.2.4). Certain ecosystems within a landscape serve as particularly efficient sinks for pollutants (6.1.3).

Biodiversity at a species or ecosystem level plays a stronger role in the relative strength of sources and sinks of trace gases. Some species and systems are particularly high sources of trace-gas emissions, such as DMS, CH₄, N₂O, and NO; (6.1.2; 6.1.6; 6.2.4; 6.2.8). Methane (CH₄) is one of the most important greenhouse gases and its production is restricted to a single group of bacteria species that require anaerobic conditions, they are found especially in wetlands and in the digestive tracts of ruminants and termites (6.1.2; 6.1.7; 6.2.4). For DMS, microbial species interactions such as grazing can have a strong influence on emission rates (6.2.4; 6.2.7), but the sensitivity to anthropogenic disturbance is not known. Other microbial species provide important sinks for CH₄ and NO.

The changes in atmospheric concentrations of some trace gases can be related in part to alterations in landscape-level diversity and human activities. One of the sources of the net addition of CO₂ to the atmosphere is land-cover conversion (i.e. change in landscape diversity) notably in the direction of tropical evergreen > tropical deciduous > temperate forests (6.1.2). Net additions of CH₄ can largely be attributed to human activities enhancing the extent of rice paddy soils, livestock, and other sources rather than one particular change in landscape diversity.

In temperate forests, changes in species composition can affect atmospheric interactions and local weather through changes in evapotranspiration and albedo (6.1.3). In desert and grassland systems, the amount of water transpired – and hence the local climate – depends very strongly on the particular complement of species present and the way in which they partition water (6.2.3). In marine systems, planktonic algae emit considerable amounts of dimethylsulphide (DMS), which subsequently have a strong influence on cloud formation (6.1.9; 6.1.12; 6.2.4).

Box 6.3-6: How is biodiversity related to soil fertility, soil erosion and the control of hazardous waste?

Soil fertility is related to soil parent material, litter type and the presence of basic microbial species richness. Therefore, within an ecosystem, species composition certainly matters, and changes in species diversity can therefore lead to changes in soil fertility. Substantial alterations in soil fertility can be driven by changes in plant species composition (6.1.6), both within and among ecosystems. Unfortunately, few data are available on microbial richness in soils, or the interactions among plant species richness per se, litter quality, soil biota and soil fertility. We know that different microbial functional groups are required for the cycling of important plant nutrients. However, at present we have little knowledge of the comparative roles of microbes within functional groups (6.2.7).

Biodiversity can affect rates of soil erosion in a variety of ways. At the species level, individual plant species, due to their growth form and canopy architecture, can play a crucial role in controlling soil erosion (6.2.5). Particularly in arid and semi-arid regions, then, reducing the diversity of plant species can accentuate soil losses through erosion. Landscape diversity resulting mainly from land-use patterns can also affect erosion rate directly (6.1.2; 6.1.4; 6.1.7). These changes largely come about through land-cover conversion, especially the transformation of forested systems to agricultural uses or pastures, but they can also come about through the intensification of agricultural management. Both changes generally have the effect of lowering the water and soil retention capabilities of the landscape, leading to increased soil erosion. Coastal forested wetlands play an important role in controlling shoreline erosion (6.1.11).

Microbial diversity can be very important for the degradation of xenobiotic compounds (i.e. hazardous wastes). It is important both for dealing with the myriad toxic compounds entering the environment in all biomes and also in cases in which microbial community interactions, such as co-metabolism, are necessary to break down a single compound (6.2.7). These phenomena can be exploited to identify specific organisms, or groups of organisms, that possess traits that could be harnessed on larger scales either to mitigate the effects of accidental contamination, or to reduce hazardous waste production in industrial processes

the appropriate components of biodiversity are maintained (Box 6.3-7). Changes in biodiversity can have direct and indirect effects on atmospheric composition, management of water, and human health. Thus, management caution in reducing diversity is indicated for both species-rich and species-poor systems, when it is important to sustain the provision of goods and services over long time scales.

Box 6.3-7: Appropriate management can enhance ecosystem services

Carbon sequestration can be enhanced by managing landscape diversity. Conversion to grassland, the most common type of forest conversion in the tropics, contributes the largest amounts of carbon emissions in those areas. Returning agricultural land to forest, or managing agricultural land more effectively to enhance soil carbon sequestration, can lead to lower emissions of trace gases, and can slow the rate at which excess carbon dioxide is added to the atmosphere.

Forest fragmentation profoundly affects biotic interactions which constitute important ecosystem services. A clear example of this is biotic pollination (6.2.6). Reducing the degree of fragmentation, perhaps by providing sufficient corridors for dispersal, might be able to maintain an acceptable level of pollination while allowing some harvesting of resources.

Acknowledgements

We thank the many contributors and reviewers of Sections 5 and 6 for their dedication to the task of producing balanced and credible assessments and their patience and persistence during numerous revisions. We are particularly grateful to the John D. and Catherine T. Macarthur Foundation during the critical initial phases and, subsequently, UNEP for their support of this work through awards to the Scientific Committee on Problems of the Environment (SCOPE). We extend special recognition to Veronique Plocq-Fichelet, Executive Director of SCOPE, for her exceptional assistance and to Anne Schram for her continuing optimism and efficiency during the protracted and intense process of preparing these Sections.

EXECUTIVE SUMMARY

Accelerating rates of biodiversity loss and the signing of international agreements, such as the Convention on Biological Diversity and *Agenda 21*, have called for the world's biodiversity to be inventoried and monitored. Yet, to date, so few organisms have been collected and named and their distributions recorded that the scale of the task is enormous.

Biodiversity inventorying is the surveying, sorting, cataloguing, quantifying and mapping of entities such as genes, individuals, populations, species, habitats, biotopes, ecosystems and landscapes or their components, and the synthesis of the resulting information for the analysis of patterns and processes. Monitoring consists of repeated inventorying over time and space and hence it measures change. This Section examines how the task of inventorying and monitoring of biodiversity can be achieved.

Data from inventorying and monitoring are essential for identifying key issues for policy and management goals. They can be used to assess priorities for conservation, for land use, for environmental impact assessments, and for informing policy-makers and the general public on the state of biodiversity. Biodiversity inventories and monitoring also provide the essential biological information for many biological sciences including systematics and population biology, ecology, and for many applied sciences, such as biotechnology, soil science, agriculture, forestry and fisheries sciences, conservation and environmental sciences.

A number of considerations are important prior to investment in inventorying and monitoring. How well these are considered will reflect on the statistical and biological validity and reliability, and comparability of the resulting data. In turn, these will determine the usefulness of the programmes concerned. For example, the temporal and geographical scale of operation need to be considered with other components of the sampling design. Particular consideration has to be given to deciding which taxa to examine (e.g. keystone, indicator, threatened, umbrella, flagship, agricultural, medical or commercial species) or what level (e.g. genes, species, population, ecosystem).

Historical collections of organisms provide extremely important baseline information on how the range, abundance and form of species may change over time. These and voucher collections are essential for the identification and verification of field data and provide a permanent record.

As such, they are a vital resource for many fields of the biological sciences.

The methods for carrying out inventories at the population, species, ecosystem and landscape level are described. Population surveys are important in understanding how that population is changing in the face of anthropogenic disturbance. Species inventories will remain perhaps the largest part of inventorying and are of value in the selection of protected and threatened areas and of ecologically and economically sensitive areas. The success of inventorying depends on natural history collections and the contribution of systematists. New techniques to analyse and disseminate systematic information are being devised.

Repeated inventorying and modelling of the resulting information provide means of monitoring biodiversity at all levels. Techniques such as censusing are important for estimating population size and hence rarity/threatened status of species. Remote sensing coupled with ground truthing is used to monitor vegetation cover, land use, forest loss and other aspects of biodiversity change at the biotope and ecosystem level. The constantly moving and three-dimensional nature of the aquatic environment (and the marine in particular) presents special monitoring problems. At present, very little monitoring of biodiversity is undertaken in some countries.

Long-term research sites and programmes provide essential information on how biodiversity changes, and are important in distinguishing anthropogenic and natural change.

Biological organisms are not restricted by political boundaries and therefore if nations are to meet national and international agreements to inventory and monitor biodiversity there needs to be sharing of scientific expertise, facilities and information. The scale of inventorying and monitoring required exceeds the capacity and infrastructure of even the most scientifically advanced nations. Inventorying and monitoring efforts can therefore be enhanced by collaboration between nations and agencies. If natural history institutions and other establishments concerned with inventorying and monitoring are to become more effective, they need to be better resourced, their collections better maintained and a new cadre of professional researchers and technicians trained and funded.

Although a number of organizations have addressed the problem of lack of coordination by proposing programmes

such as DIVERSITAS and Systematics Agenda 2000, these are, as yet, largely only programmes on paper. If these and other programmes are to become plans for action and then implemented then they need to be integrated into a Global

Inventorying and Monitoring Programme which will link with others, such as GTOS, GCOS and GOOS which monitor changes in physical parameters of the Earth.

7.0 Introduction

7.0.1 Inventorying and monitoring

7.0.1.1 Definitions

Inventorying is the surveying, sorting, cataloguing, quantifying and mapping of entities such as genes, individuals, populations, species, habitats, biotopes, ecosystems and landscapes or their components, and the synthesis of the resulting information for the analysis of processes. The presence/absence, relative abundance, and patterns of variation of these biological entities span spatial scales from nanometres to countries, continents, ocean basins and the entire biosphere.

No inventory is ever complete as there will always be additions of new entities and new variation (through immigration, birth or mutation) and disappearances of entities (through emigration, death or extinction) as well as changes in abundances. Inventories, the result of inventorying, are more than simply lists of names and numbers; they also involve the extensive application of systematics, ecology, biogeography and management. Inventories give a snapshot of the state of biodiversity and identify key variables and bioindicators. Inventories also provide baseline information for the assessment of change, and they apply to all ecosystems from fully natural to intensively managed.

Monitoring consists of intermittent (regular or irregular) surveillance to ascertain the extent of compliance with a predetermined standard or degree of deviation from an expected norm (Hellawell 1991). Goldsmith (1991) points out that monitoring is usually goal-orientated and designed to reveal changes in a particular parameter or parameters. It is repeated at intervals (mostly regular) and often provides a baseline for recording changes in the future. Monitoring of biological diversity aims to develop a strategic framework for predicting the behaviour of key variables in order to improve management, increase management options and provide an early warning of system change. Success in monitoring depends on the factors listed below (di Castri *et al.* 1992; Solbrig 1991; and see Chapter 7.1):

- being clear on the spatial and temporal scales of investigation and management;
- having a keen awareness of the time scale of a project and its feasibility within that time frame;
- using an appropriate taxon or various taxa to provide the information needed to illustrate pertinent changes;
- using methodologies, including statistics, that are appropriate and efficient to the study or management site, while also providing comparable results from other sites locally, regionally or globally;

- standardizing data collections and statistical analyses;
- maintaining voucher collections of the subject organisms;
- using existing data where they are valid; and
- ensuring that not only appropriate biotic, but also abiotic and human variables are recorded and put into the appropriate statistical framework.

7.0.1.2 Contexts

It is important to establish the linkages between science and management. Inventories provide the basic science while monitoring measures *change* and guides management. Such management is dynamic, as it responds to the monitoring output from inherently dynamic ecosystems.

Inventorying and monitoring have previously been encompassed by such terms as surveying and describing. For example, in *A Biological Survey for the Nation* (NRC 1993) the term ‘survey’ is used to include the ‘inventorying, mapping and monitoring of biotic resources; performing basic and applied research on species, groups of species, populations and ecosystems; and providing ... scientific support and technical assistance...’. But today inventorying is coming to mean something more precise and with greater scientific underpinning.

Recent international agreements and strategies have recognized the need to inventory and monitor biological diversity and have called on countries to initiate inventorying and monitoring programmes.

- Article 7 of the United Nations Convention on Environment and Development requires signatory parties to ‘identify components of biodiversity important for conservation and sustainable use... and monitor, through sampling and other techniques, the components of biological diversity identified’. It also calls for signatories to ‘identify processes and categories of activities which have or are likely to have significant adverse impacts on the conservation and sustainable use of biological diversity, and monitor their effects’ and to ‘maintain and organise ... data derived from identification and monitoring activities’ (Johnson 1993). This will involve a combination of the assembly of existing data, generation of new data, and organization to ensure that the resulting information is both usable and easily accessible (Glowka *et al.* 1994). However, the Biodiversity Convention does not require signatory nations to provide a *full* inventory of all the components of their biological diversity but only to identify biodiversity components that are important for conservation and sustainable use.

- Chapter 15.5 of *Agenda 21* calls on signatories to ‘undertake country studies or use other methods to identify components of biological diversity important for its conservation and the sustainable use of biological resources ...’ and to ‘promote, where appropriate, the establishment and strengthening of national inventory ... related to biological resources at the appropriate level’. Chapter 15.6 calls for the development of ‘methodologies with a view to undertaking systematic sampling and evaluation on a national basis of the components of biological diversity identified by means of country studies’ and to ‘initiate or further develop methodologies and begin or continue work on surveys at the appropriate level on the status of ecosystems and establish baseline information on biological and genetic resources, including those in terrestrial, aquatic, coastal and marine ecosystems, as well as inventories undertaken with the participation of local and indigenous people and their communities’ (Johnson 1993).
- The *Global Biodiversity Strategy* (WRI/IUCN/UNEP 1992) recommends that an early warning network be established to ‘monitor potential threats to biodiversity and mobilize action against them’ [Action 4].
- A global strategy addressing marine biodiversity (Norse 1993) suggests the establishment of a global monitoring network on ecological processes to provide information for management and to provide warning of ‘undesirable changes’.
- Inventory and monitoring efforts are also central to the activities described in *Guidelines for Country Studies on Biological Diversity* (UNEP 1993). Country Studies provide an information base from which nations can develop biodiversity action plans, as requested by the Biodiversity Convention. Numerous other planning documents make the same point.

7.0.2 Section outline

Because of the interdependence of inventorying and monitoring the two subjects are treated together. We deal with biological diversity at various levels and from various perspectives, and discuss aspects of inventorying and monitoring for each. The Section is divided into four chapters.

(1) Why inventory and monitor biodiversity?

- Decisions for investigating the global loss of biodiversity are dependent on science-based analyses of the changing states of species groups, populations, communities and the ecosystems they inhabit.

This chapter discusses the need for inventorying and monitoring the world’s biological diversity at different biological levels. In particular, it outlines the necessity for scientific research and guidance for policy and management decisions.

(2) Scales, planning and approaches to inventorying and monitoring

- Assessments of the changing demographics of biodiversity around the globe require comparable and quantifiable biological and environmental data related to the causes and effects of the changes.

This chapter outlines approaches to inventorying and monitoring, and the variables that are to be taken into account prior to such an undertaking. It identifies those issues that are critical to the success of inventorying and monitoring efforts and addresses the important issue of spatial and temporal scales of analysis. Additional considerations prior to any investigation, such as collection of voucher specimens and the standardization of methods, are discussed.

- The time, effort and funds required to inventory and monitor global biodiversity will need to be based on the most cost-effective and efficient scientific methodologies presently available.

This extensive and technical chapter also discusses the methods for compiling inventories and for monitoring different levels of biological diversity (and is complemented by the methods already described in Section 2). It also considers the taxa and ecological indicators that might be used as foci for research and management. There is detailed discussion on points and areas that are making particularly important contributions to biodiversity assessment using new technologies. Where well-established and traditional methodologies are mentioned, references are given to direct the reader to the appropriate, useful literature.

(3) Integrated approaches

- National, regional and international collaborative efforts that are multidisciplinary and multisectorial will improve the effectiveness and efficiency of the inventorying and monitoring effort.

This chapter investigates national and international efforts to co-ordinate inventorying and monitoring. Such co-ordination is essential if resources, including time, money and personnel are to be used to the full. Good co-ordination also prevents certain geographical areas from being neglected, while also avoiding repetitive efforts being made in others. The integration of inventorying and monitoring

of biological diversity with that of physical variables is addressed, as is the co-ordination of inventorying and monitoring for conservation.

(4) Capacity-building

- Presently the scientific, technical and support infrastructure required for improving global biodiversity assessments requires augmentation in staff and facilities, particularly in developing countries where the biological and economic losses will be greatest if global biodiversity continues to become degraded in the absence of focused mitigating actions.

This chapter discusses the urgent need to build human and institutional capacity for inventorying and monitoring. In particular, it examines ways of developing physical infrastructure and human resources.

7.0.3 Summary

- Recent international agreements and strategies have called for increased inventorying and monitoring of biodiversity.
- Inventorying is the surveying, sorting, cataloguing, quantifying and mapping of entities such as genes, individuals, populations, species, habitats, biotopes, ecosystems and landscapes or their components, and the synthesis of the resulting information for the analysis of patterns and processes.
- Monitoring is the intermittent (regular or irregular) surveillance to ascertain the extent of compliance with a predetermined standard or degree of deviation from an expected norm.

7.1 Why inventory and monitor biodiversity?

7.1.1 Introduction

Biodiversity inventorying and monitoring provide fundamental and essential biological information used by many basic scientific disciplines (e.g. systematics, population biology, behaviour, ecology and other fields of comparative biology) and many applied sciences (e.g. biotechnology, soil science, agriculture, forestry and fisheries sciences, conservation and environmental sciences) (see Box 7.1-1).

Scientists know enough about the overall distribution of threats to biodiversity to be able to guide the allocation of resources to support biodiversity assessments and recommend direction for sustainable resource use. Experience shows that where resources are wisely and systematically used to inventory and monitor biodiversity, challenges can be met. An example is the application of adaptive management strategies which hold promise for achieving sustainable use of fishery resources and the maintenance of biological diversity. Risk assessments that consider availability of resource abundance and productivity have become an integral part of scientific advice to managers. Among the relatively new fisheries for which access and fishing effort have been controlled from the start of fishing, leading to sustainable biomass yields, are those of the Falklands Islands and the bottom fisheries of the northwest shelf system of Australia.

The identification and monitoring of biological diversity are regarded as being essential for supporting Articles 8, 9 and 10 of the Convention on Biological Biodiversity (Glowka *et al.* 1994) which consider the *in situ* and *ex situ* conservation of biological diversity and sustainable use of its components. Glowka *et al.* (1994) point out that the results of identification and monitoring projects are important for:

- developing strategies, plans and programmes [Article 6(a)];
- integrating conservation and sustainable use into sectorial and cross-sectorial plans, programmes or policies [Article 6(b)];
- undertaking environmental impact assessment [Article 14(a) and (b)]; and

Box 7.1-1: The use of inventories and monitoring data in basic and applied sciences (*based on: NRC 1993*).

Inventorying and monitoring of biological diversity provide information that may be used:

- to provide a basis for the scientific research necessary for understanding the world in which we live (both inside and outside protected areas),
- to define the current and future options available for meeting human needs, and
- to guide immediate and long-term management, policy and decision-making.

Areas in which inventories and monitoring activities are important include:

- providing information for determining and conserving biological diversity;
- providing information necessary for the sustainable management of natural resources;
- identifying economically valuable products from wild species (bioprospecting);
- maintaining or increasing the productivity of agricultural systems through the identification of (i) new varieties or new species of use to humans and (ii) beneficial and harmful organisms;
- improving human health through the identification of pest organisms and beneficial organisms;
- understanding ecosystem processes so that the ecological services essential for human survival can be maintained;
- defining the impact of human activities on biodiversity so as to help reduce undesirable effects on the environment;
- understanding the potential effects and impact of climate change and other forms of natural environmental change;
- determining the aesthetic benefits of diversity so as to preserve the quality of human life.

- negotiating access agreements, including benefit-sharing [Article 15(7)].

Actions affecting biodiversity and natural resources are often based on inadequate information. There are three main reasons for this:

- the data necessary for informed decision-making are unavailable, incomplete or unreliable;
- the data are not presented in a format that policy-makers and managers can use, and
- the data are incorrectly interpreted.

Given the limited funds available for data collection, analysis of *which* information is useful to decision-makers (defining the audience and determining their needs) is critical for knowing what should be inventoried and monitored (see Chapters 7.2 and 7.3). Various models exist that help put such information into a framework useful for

decision-makers. For example, one of the best known, the pressure–state–response model helps to conceptualize what questions need to be addressed by inventory and monitoring programmes (Figure 7.1-1).

Monitoring questions framed around the pressure–state–response model include:

- What are the pressures on the system in question?
- Which factors affecting biodiversity are changing, or have changed, over time?
- Are policies to manage a given species/population/ecosystem working?
- At what rate is the pressure operating?

7.1.2 The rationale for inventorying and monitoring biodiversity at different spatial and temporal scales

Inventorying and monitoring need to be carried out at different geographical scales, from local to global,

Figure 7.1-1: Pressure–state–response model. An inventory can determine the *state* of a particular system at a given time (e.g. the number of individuals in population, the number of species in an area, or the type and extent of biotope types within a region). Inventories can also document *pressures* on given elements of diversity, but these are often only visible over time. Monitoring is critical for determining and defining pressures on a given element, changes in the state of that element and *responses* both to existing pressures and to management and policy interventions.

depending on the problems that are being addressed (see Chapter 7.2). Examples are given in Box 7.1-2.

Two major areas where monitoring is applicable across varying geographical scales are: (1) The assessment of the effectiveness of biodiversity management. For national, regional or park programmes designed to preserve or increase biodiversity or to optimize biodiversity in systems managed for other goals (e.g. plantations), monitoring is a way of documenting whether the stated goals were, or are

being, achieved. (2) The need for an early-warning system of impending adverse change. The objective here is to develop a monitoring system that is sensitive to unusual changes in biodiversity before they become too critical.

Similarly, the kinds of problems that are being examined, the level of assessment, and the groups of organisms or perturbations to ecosystems will determine the time scale for inventorying and monitoring. For some questions it may be appropriate to carry out inventories on a daily basis to monitor daily changes, whereas for others it may be necessary to carry out inventories every year, every ten years, or longer.

7.1.3 The rationale for inventorying and monitoring biodiversity at different biological levels

7.1.3.1 At the genetic level

Biochemical and molecular data are increasingly useful for assessing and managing regional diversity in natural populations. A conceptual framework for developing conservation strategies is emerging from the recently developed field of ‘conservation genetics’, and numerous genetic techniques are available for characterizing wild and cultivated populations or populations managed in captivity (Hillis and Moritz 1990; Avise 1994). Molecular methods can be used to survey genetic variability at three levels of organization:

- individual organisms within populations;

Box 7.1-2: Examples of uses of information from the inventorying and monitoring of biodiversity at different spatial scales.

Site/local level

Mining and manufacturing industries that are environmentally sensitive use maps of specific areas to determine the precise and optimal location of activity to minimize disruption of important ecosystems.

Sub-national level

State government agencies use information on protected areas and ownership, species distribution and natural vegetation cover to determine gaps in protected area coverage and to propose new areas for protection (Csuti 1994; Rebelo and Siegfried 1990).

National level

Ministries and government agencies in many countries monitor population changes within their fisheries to set annual catch levels to avoid over-exploitation (e.g. Elst 1993).

Regional and continental

Agencies use information on species distribution, threat and other biodiversity data to prioritize where to allocate conservation funding (e.g. Olson and Dinerstein 1994).

Global

The World Trade Monitoring Unit of the World Conservation Monitoring Centre, a non-governmental organization, uses data on international trade of wild species to monitor compliance with the CITES treaty.

Box 7.1-3: The use of genetic surveys: examples of research questions at different levels (*adapted from: Hillis and Moritz 1990; Baverstock and Moritz 1990; Avise 1994*).

Individuals within populations

How much genetic variation is present in the population?
 What are the parentage/kinship relationships among individuals?
 What form of mating systems exist in the population?
 Is there evidence for inbreeding and reason to suspect that individuals may be suffering from inbreeding depression?
 For sex-linked markers, what is the gender of an individual?
 Can the genetic effects of sex-biased dispersal be detected?
 What are the geographic origins of migratory individuals?

Populations and species

Are there genetically distinct evolutionary lineages within a species?
 What is the degree of genetic subdivision among populations?
 What are the biogeographic correlates of genetic subdivision?
 What is the degree of gene flow between populations?

Among-species comparisons

What are the phylogenetic relationships among species?
 What is the extent of genetic differentiation among species?
 Are species limits correctly understood?
 Can individuals or populations be distinguished from closely related species?
 What are the relative ages of divergence among species?
 What are the adaptive components of morphological traits among species?

- the species-level and populations within species;
- among-species comparisons.

Some typical questions addressed at each level are summarized in Box 7.1-3. At the first level, genetic surveys can identify individuals that may have suffered reductions in genetic variability because of large reductions in population size. Reduced levels of genetic variability can often lead to inbreeding depression, especially in species whose life-history patterns have historically produced large population sizes. Inbreeding depression may be due to the homozygosity of recessive deleterious genes or to a reduction in genetic variability itself, and may be important in small populations (see Section 4.2). Inbreeding, for example, can lead to the loss of disease resistance or to the inability of the populations to adapt to changing environments. All of these disruptive effects can make small populations more vulnerable to extinction.

Geographic surveys are important for identifying appropriate groups of genetically similar populations for conservation or management. In migratory species, such as sea turtles and salmon which home to natal areas to breed, genetic methods can be used to identify the origins of individuals from threatened breeding areas that are harvested or caught incidentally in high-seas drift-net fisheries. In devising a conservation strategy for a

threatened species, it is important to conserve not just a few representatives of a species, but also to preserve a wide range of the species' genetic variability. Often regional groups of populations represent unique adaptations to local habitats that merit conservation. Locally adapted gene complexes, however, can be disrupted by inadvertent introductions of foreign genes by translocations of individuals, and this can lead to outbreeding depression (see Section 4.2). Identification of genetically distinct groups is especially important in the *ex situ* management of captive populations in zoological gardens or of artificially propagated semi-wild populations.

At the species level, genetic data can be important for identifying morphologically cryptic species which may go unrecognized or which may be inappropriately mixed with genetically unrelated populations. The systematics of many commercially important plants and animals are still poorly understood. Such information can be used, for example, to search for genes in closely related species that may be used to increase production or to enhance disease resistance. Phylogenetic studies of cultivated species and their wild relatives are important for identifying the closest relatives of domesticated strains in order to preserve important genetic resources. The effective enforcement of international agreements on the trade in rare and threatened species (such as CITES) will also require better information on species limits and identifications (Pain 1994). Genetic data may also

Box 7.1-4: Monitoring of genetic variation.

Genetic variation and endangered species

The New Zealand kakapo, *Strigops habroptilus*, is a large, nocturnal, flightless parrot. Once widespread across New Zealand, populations became confined to two areas, the Fiordland and Stewart Island. Approximately 45 individuals inhabited Stewart Island, including 18 females, while the Fiordland population comprised only 5 male birds. In 1982, in an effort to protect the species, 22 individuals were moved to Little Barrier Island, an area free of predators (Triggs *et al.* 1989). It is now important to maintain genetic variation both within and between these populations if the kakapo is to survive and respond to future environmental changes. Using blood samples from a number of individuals from each population, allozymic variation was examined. All three populations were found to be passing through a genetic bottleneck, likely to cause both loss of heterozygosity and allelic diversity within the Stewart Island and Little Barrier Island populations and genetic differentiation between them (Triggs *et al.* 1989), while the all-male Fiordland population is destined for early extinction. However, from the findings it was also possible to suggest a management strategy for the kakapo, including the reciprocal transfer of one young bird per generation between the populations, to maintain them as a single effective genetic unit and reduce inbreeding. Monitoring of the level of genetic variation within each population, and genetic differentiation between populations, will be necessary to gauge the success of this plan. It should be pointed out, however, that genetic bottlenecks are not the only problem facing the kakapo. Predation of these relatively vulnerable birds by small, introduced mammals may be an even greater threat (Prowlesland *et al.* 1992).

The only surviving genus (*Sphenodon*) of one group of iguana-like reptiles, which flourished during the Triassic Period, inhabits several islands along the coast of New Zealand. Although populations of the genus were protected in 1895 by legislation, the significance to conservation of genetic and morphological patterns of variability among the individuals was not fully recognized until recently. The extinction of 10 of 40 populations over the last century was considered to be of no great importance by managers, because the other populations were widespread and reasonably stable. Contrary to the perceived genetic uniformity of these populations, a genetic analysis of 24 populations (Daugherty *et al.* 1990) detected evidence for two species. One species was further subdivided into two subspecies with several populations in each subspecies, but the other was represented by only 300 individuals at a single locality and may have not otherwise have been afforded protection from extinction.

Genetic variation and the development of domestic livestock breeds

An enormous amount of animal diversity is represented by the different breeds of domestic livestock (see Sections 2.2 and 3.1). With careful inventorying and monitoring, this diversity may be exploited to improve the characteristics and production of breeds. For example, the Sahiwal dairy breed of cattle, from Pakistan, was introduced into Australia to confer tick resistance on Friesian herds. The Finnish Landrace sheep has been crossed with the Dorset Horn to produce ewes which, when mated with Suffolk rams, produce good meat lambs. Dairy cattle from Europe and North America have been crossbred with the Zebu cattle of India and South America to increase milk yields (WCMC 1992). New genetic mutations, occurring within an established breed, may also be exploited. For example, in 1931 a mutation produced a very hairy fleece on a New Zealand Romney lamb. The fleece produced when this gene was homozygous was perfect for carpet manufacture and sparked the development of both a new industry in the area and a new breed of sheep, the Drysdale (WCMC 1992).

Genetic markers for tracing the origins of individuals

Genetic markers have been used to identify the origins of individuals on the high seas that are homing to threatened spawning areas. Chum salmon are one of seven species of salmon in the North Pacific Ocean that spawn in freshwater streams from where young fish swim into the ocean and migrate in a large gyre around the North Pacific. Research agencies in Japan, Russia and the United States joined in a standardized study to estimate allele frequencies for several allozymes in chum salmon spawning areas located around the rim of the North Pacific and have used these genetic baseline data to identify the continents of origin of salmon caught in international waters (Winans *et al.* 1994).

In a study of loggerhead sea turtles (*Caretta caretta*) caught incidentally by drift nets on the high seas, Bowen *et al.* (1995) used nucleotide sequence variability in mitochondrial DNA to determine the origins of the turtles. The only known beach-spawning areas of loggerhead turtles are in Australia and Japan even though juveniles apparently traverse the entire Pacific Ocean and feed in waters off Mexico. Their statistical analyses of the mitochondrial genotypes showed that juveniles collected in mid-Pacific drift nets and off Mexico originated from both Japan and Australia. Such results confirm the importance of protecting mid-ocean juveniles in their migrations to distant feeding areas.

be of value in policing the purported 'captive breeding' of species of high economic value. Many of the appropriate genetic technologies are discussed in Section 2.

The degree of relationship between pairs of diploid species can also be inferred from the analysis of chromosome pairing in their hybrids. Differences in chromosome number and morphology are generally indicative of strong barriers to gene exchange. Phylogenetic relationships can also be inferred from the appearance and behaviour of chromosomes at meiosis. Genetic data are also important for genetic engineering. For example, by synthesizing naturally occurring polyploid species it can be shown how such polyploids may have evolved from their putative diploid ancestors.

Box 7.1-4 illustrates examples of the importance of monitoring at the genetic level.

7.1.3.2 At the population level

Many of the above genetic arguments relate also to inventorying and monitoring at the population level. The monitoring of population dynamics can result in the development of sound conservation strategies for particular systems, and produces generalizations of potentially wide applicability (Soulé and Kohm 1989). Such monitoring must be long-term if it is to generate data that will enable detection of a signal (such as declining population size) over the noise (or random fluctuations) inherent in most systems. Conservation recommendations based on short-term studies often have to be reconsidered in the light of subsequent information. For example, rare events such as a drought or an epidemic may be the key to the long-term population dynamics of a species (Soulé and Kohm 1989).

The identification and monitoring of populations provide important information for the characterization of rarity and threat status. The new *IUCN Red List Categories* (IUCN 1994) include population status and rate of decline among the criteria for categorizing species as 'Critically Endangered', 'Endangered' or 'Vulnerable'. Using quantitative methods for such characterizations provides a formalized objective procedure that can be repeated and compared and, most importantly, allows for consistent monitoring of threatened status. Nevertheless, qualitative assessments based on the evaluations of experts can also be useful in determining the degree to which a population may be threatened. When surveys are repeated over time, population trends can be assessed, which is one of the tenets of the new IUCN Categories of Threat (see Section 13.4.3).

Demographic information is also important in determining Minimum Viable Population (MVP) and Population Viability Analysis (PVA), two approaches for dealing with the problems of small population size. The MVP is the population size that provides a given probability of persistence of the population for a given amount of time (e.g. a 95% expectation of persistence without loss of fitness for several centuries), while the PVA

is the probability that a population will persist for some designated period. These methods are further discussed in 7.2.6.5 and in Section 4.4 (see also Fiedler and Jain 1992 for some practical applications).

Population inventorying and monitoring provide information for determining sustainable harvests and yields. Harvesting is essentially a consumer-prey relationship where humans are the consumers. Humans harvest a vast range of life forms (e.g. molluscs, fish, trees, game animals, herbs) and, in most cases, exploitation involves the complete removal of the individual. Less commonly, parts or products of the organisms are harvested (e.g. leaves, fruits, resins, wild honey, bird feathers). Analyses of harvest and yield involving individuals may be quantitatively similar to those involving organism parts or products, because partial harvest may often affect individual survival and demographic traits. Models of sustainable harvesting require both time series of population abundance (relative or absolute) and estimates of demographic parameters (Clark 1981; Walters 1986; Getz and Haight 1989; Royama 1992). Substantial yields are most difficult to sustain if a population is fluctuating. It is important also that models are not based on unrealistic ideals such as assumptions of a constant environment. Details of population methodologies are discussed in 7.2.6 and 7.2.7.

7.1.3.3 At the species level

Scientific information resulting from species inventories supports a wide range of activities. For example:

- For a nation, knowing the identity and geographical distribution of its species is perhaps the most important information available in its attempts to preserve and use its biodiversity. This knowledge comes primarily from inventories of various kinds and provides basic knowledge for day-to-day management decisions regarding natural resources.
- Species inventories across global, regional or national levels are important for establishing patterns of diversity and identifying areas of endemism (see Section 3.3), two primary components in evaluating areas for protected status.
- At more local levels, species inventories are required elements for meeting management objectives for protected areas (UNEP 1993), including maintaining ecosystems and biological diversity, conserving genetic resources, monitoring change, providing for sustainable economic uses such as hunting, fishing, recreation, tourism and forestry, and facilitating education and research.
- New taxa and new biological material of described

taxa collected during the inventory process are essential for clarifying species identifications and relationships (Mound and Gaston 1993). Inventories of small invertebrates or microorganisms often contain a high proportion of undescribed species.

- Inventory activities result in the accumulation of scientific specimens, tissues and other biological material, preserved or living, which help to build the natural history collections of museums, botanical gardens and zoos and provide a basis for scientific studies and conservation management well into the future. Tissues and other living material increase the holdings of gene and tissue banks, seed banks, culture collections and other institutions concerned with genetic resources.
- Studies of specimens collected during inventories yield data useful for resolving the phylogenetic relationships of species, which, in turn, are essential for building predictive classification systems and permit the estimation of character diversity for comparison of biotas (Williams *et al.* 1995). These relationships can be used to help prioritize areas for conservation or other land management decisions (e.g. Vane-Wright 1993).
- Scientific reports, papers, distributional lists and systematic monographs, produced following systematic analysis of natural history collections, may in turn form the basis for many products useful to a general audience, including pamphlets, field guides and photographic guides.
- Information from species inventories may be used in biogeographical analyses to understand patterns of diversity, the processes that have produced the Earth's biological variety and present-day distributions and to predict how biodiversity may change with altered environments. Biogeographical information may also assist in discovering the origins of agricultural pests and diseases, leading to the identification of their natural predators and parasitoids.
- Inventories provide ecologists with data about the presence or absence of species in an area, basic information which is essential for them to begin to understand community structure, function and processes.
- Inventories and the collections they produce also expand the scientific study of the region in question. Information from specimens and from field notes can be incorporated into Geographic Information Systems (GIS) to provide a more sophisticated basis for resource

management. Furthermore, information associated with specimens, including behavioural and ecological data, provides an essential record available to all scientists that were not part of the inventory process itself.

- Species inventories provide the foundation for future industrial applications, particularly those associated with bioprospecting (Reid *et al.* 1993). Likewise, the discoveries that result from inventories can support agricultural and forestry programmes.
- Finally, inventories contribute to the education and training of scientists, and therefore help build biodiversity science capacity. Moreover, in the long run inventories invariably contribute to general public education about biodiversity and conservation.

Although the advantages of inventorying biodiversity are clear to many scientists and non-scientists, some workers have questioned the relevance of some of the products (in particular species lists) to practical problems of conservation (Renner and Ricklefs 1994). Their concern is that such efforts may undermine rather than support the scientific discipline of systematics. This is, however, a minority view. Box 7.1.5 illustrates some examples of the usefulness of inventories at the species level.

7.1.3.3.1 Species turnover in ecosystems. Changes in species diversity occur naturally over time in all communities and ecosystems. Human disturbance may change the rate and/or direction of these changes. However, because the dominant organisms in many ecological systems are long-lived, many important changes in communities and ecosystems are too slow for us to sense directly and only long-term monitoring can reveal such important changes (Hellawell 1991; NRC 1993). Species-based monitoring programmes can document natural patterns of change (positive or negative), or lack of change, to establish a baseline for understanding the impact of natural disturbance on species composition and abundance in ecosystems. Once a baseline has been established, it can be used to detect changes in biodiversity (variations from the norm) that result either directly or indirectly from human disturbance. Monitoring can also be used in a predictive manner to test anticipated change, for example as a function of global warming models (Solbrig 1991). Thus, by knowing how different species respond to different stresses, we can predict the extent of local species extinction and replacement and, therefore, ecosystem change (Soulé and Kohm 1989). It is also important that we identify such changes early enough for corrective actions to be taken while multiple options are still available. With reduction in the number of options, the expense of remedial action increases.

Details of species inventorying and monitoring are discussed in Sections 7.2.8 and 7.2.9.

Box 7.1-5: Inventorying of biodiversity at the species level: the value of new species.

Viral resistance in wild maize

In the late 1970s, plant systematist Rafael Guzman discovered a species of perennial teosinte, or wild corn, in the Sierra de Manantlán mountain cloud forests of southwestern Mexico. This species, later named *Zea diploperennis*, was found to be resistant to the seven major viral diseases that infect its cultivated relative, *Z. mays* (Iltis 1988). Furthermore, *Z. diploperennis* was found to have the same chromosome number as *Z. mays* and it has been possible to transfer some of the viral resistance to cultivated corn. Four new commercial lines have already been produced and, considering that corn is one of the three most important crops world-wide, with an annual value of nearly US\$60 billion, this find is estimated to have a potential annual value of US\$4.4 billion. This example emphasizes the importance of plant inventories and systematic research in agricultural productivity.

Utilizing the biodiversity of tropical forests

One strategy for the future preservation of large tracts of tropical forest might be to set up 'extractive reserves' like those of the Brazilian Amazon. Currently the two main products of such areas are rubber and brazil nuts. Inventorying the many plant products used by indigenous peoples may enable these species to be supplemented by others, making extractive reserves more economically viable (Prance 1990). In Amazonia, new products that can be harvested or extracted without felling might include copaiba balsam, from trees of the genus *Copaifera*. Used locally as a medicine and scent, copiba balsam has been used abroad in varnishes and may also have a future in the cosmetics industry. Similarly, the large, oily seed of the androbia tree, *Carapa quianensis*, may be useful for cosmetics. Palm trees may be exploited for their fruits, their nut oil or fibres from their leaves. Nuts of the babassu palm, *Orbignya phalerata*, may be used as fuel and for making charcoal. Many cosmetics have already been produced using ingredients from tropical forests. A more unusual example, however, has been the recent marketing of Ben & Jerry's Homemade Ice Cream flavour, Rainforest Crunch.

Tomato cultivation

In December 1962, whilst on an expedition in the Peruvian Andes, botanists Hugh Iltis and Don Ugent collected a 'tangled, yellow-flowered, sticky-leaved, ratty-looking, wild tomato' (Iltis 1988). The fruits of this plant were small and green-and-white striped. Some of the seed was sent to tomato geneticist Charles Rick, at the University of California, Davis, to grow. After fourteen years of research Professor Rick identified the plant as a new species and named it *Lycopersicon chmielewskii*. When crossed with a commercial variety of tomato (*L. esculentus*) several strains (or hybrids) with larger fruit and improved colouring were produced. More importantly, the fruits of the crossbred plants had a greatly increased content of soluble solids, including fructose, glucose and other sugars. The value to the tomato industry of the genes from this one new species is estimated to be US\$8 million per year (Iltis 1988).

Rattans

Following timber, rattans (Palmae) are the second most important source of export earnings from tropical forests. The trade in rattan products accounts for more than US\$1 billion annually (Plotkin 1988). China, Indonesia, India, Malaysia, the Phillipines, Sri Lanka and Thailand all support major rattan industries, providing employment for at least 0.5 million people. The international market uses rattans in the manufacture of cane furniture, while domestic markets use rattan in mats, baskets, traps, dyes and medicines. Since 90% of the rattan used in industry comes from the wild, this exploitation has contributed to a decline in the major commercial rattan species as well as those valuable to local markets. Most of the 600 species of rattan are native to South and Southeast Asia; 104 of these may be found in the Malay Peninsula alone, 38% of these being endemic. Of these 104 species, 98 are categorized as threatened or endangered. Research is now under way to investigate the taxonomy and silviculture of Malaysian rattans to bring some of them into cultivation, in an effort to lessen the pressure on wild species and to increase the economic benefits derived from this industry (Plotkin 1988).

7.1.3.4 At the ecosystem and landscape levels

Inventorying ecosystems and monitoring changes in their character and processes are essential for distinguishing short-term variation from long-term patterns (Chernoff 1986). Ecosystem monitoring is important for management and policy making in many ways, including:

- understanding ecosystem processes;
- understanding the effects of landscape fragmentation, habitat destruction and other forms of disturbance;
- distinguishing where population trends are due to

- natural fluctuations as opposed to anthropogenic factors;
- predicting the possible effects of global climate change;
 - predicting the ecological changes that may follow the extinction of one or more key species or taxonomic groups;
 - measuring changes in Earth cover and land use and the impacts of these on biodiversity.

Land usage can change rapidly, particularly in agricultural and urban landscapes (Forman and Gordon 1986). Also, ecosystem limits can extend or shrink over time even within protected areas. The problem of ‘shifting mosaics’, especially within protected areas, can be better understood with information on the distribution of different biotope and ecosystem types from remote sensing (see Section 7.2.10.4). The dynamic characteristics of a watershed, for example, are best inferred through this process and the resultant maps provide information on features such as changes in levels of water bodies and river courses. Likewise, the extent of littoral vegetation on beaches, soil binders in sand dunes, and mangrove vegetation along

estuarine shorelines, all of which are important in regulating soil erosion, can be represented and monitored by remote sensing.

Within the nearshore areas, and extending around the margins of global landmasses, species in coastal ecosystems are being subjected to increased stress from toxic effluents, habitat degradation, excessive nutrient loadings, harmful algal blooms, emergent disease fallout from aerosol contaminants, and episodic losses of marine resources from pollution effects and over-exploitation (see Section 6.1.9). The long-term sustainability of biodiversity of resource species in coastal ecosystems as sources for healthy economies appears to be diminishing. A growing awareness of problems such as these has accelerated efforts to assess, monitor and mitigate the stresses on coastal ecosystems (Sherman 1994).

Box 7.1-6 illustrates the importance of monitoring in marine ecosystems. Details of ecosystem and landscape monitoring are given in 7.2.10, while monitoring of the rehabilitation of degraded ecosystems is discussed in Section 11.3.2.2.

7.1.4 The rationale for inventorizing and monitoring biodiversity inside and outside protected areas

There are two aims of monitoring in protected areas: (1) to provide managers with the information they require for

Box 7.1-6: Monitoring in marine ecosystems.

A critical feature of marine ecosystem monitoring strategies is the development of a consistent long-term database for understanding interannual changes and multi-year trends in biomass yields. For example, during the late 1960s when there was intense fishing within the Northeast US Continental Shelf ecosystem, marked alterations in fish abundances were observed. The finfish biomass of economically important species (e.g. cod, haddock, flounders) declined by approximately 50%. This was followed by increases in the biomass of small elasmobranchs (dogfish and skates), and led to the conclusion that the overall carrying capacity of the ecosystem for finfish did not change (Anthony 1993; Collie 1991). However, the excessive fishing effort on the more highly valued species allowed for the lower-valued elasmobranchs to increase in abundance. Management of the marine fisheries will need to take these kinds of species dominance shifts into account in developing strategies for long-term economic sustainability of the fisheries.

Species shift and abundance of small elasmobranchs (dogfish and skates) on Georges Bank in the North-east Continental Shelf ecosystem of the United States compared with the North Sea ecosystem (adapted from Anthony 1988).

effective management, and (2) to provide information as part of national and international monitoring programmes.

The first requires each protected area to have a programme that identifies the monitoring needs and the resources available. It also specifies the type of monitoring activity, and where and when it should be carried out. The second objective requires guidance and support from the appropriate national and international authorities, specifying which programmes to follow and identifying appropriate methodologies (Lucas 1992). Although these stipulations were formulated for protected areas, they are equally applicable to many areas without protection.

7.1.4.1 Management effectiveness in protected areas

There is no global review of management effectiveness, but experience and reviews of protected areas in South America and the Caribbean suggest that monitoring the effectiveness of management is extremely important. The need for long-term monitoring is therefore clear. Protected areas have a legal designation and, usually, a set of management objectives set out either in legislation or in a management plan. Programmes are needed to monitor the degree of implementation of these objectives and the effectiveness of management practice, in order for action to be taken to correct both inappropriate management and action that is having unforeseen results. It may be sensible also to have the involvement of independent advisors who assist monitoring activity or carry out periodic 'peer' review.

Monitoring in protected areas assists the development of management strategies (Spellerberg 1991). For example,

data from aerial photographs and visitor surveys were used to quantify changes and provide a database for long-term monitoring of Rondane National Park in Norway (Fry *et al.* 1992).

Protected area experts meeting at the Fourth World Congress on National Parks and Protected Areas identified four criteria important in the assessment of management effectiveness:

- clear management objectives,
- availability of resources to implement the objectives,
- achievement of objectives, and
- monitoring of implementation of objectives.

It is also necessary to develop and adopt internationally accepted guidelines for assessing management effectiveness. Once developed, the agreed methods/guidelines need to be tested further, disseminated, and their implementation encouraged.

7.1.4.2 Status of identified features in protected areas

Most protected areas are established to conserve key features, whether these are species, biotopes, ecosystems or landscapes. There is a need to monitor the status of these features using appropriate methods so as to manage them effectively. An example of such monitoring programmes is that of the Kruger National Park in Box 7.1-7.

Box 7.1-7: Monitoring of one of the world's largest game parks: the Kruger National Park, South Africa (from: Kruger National Park 1994).

The mission of scientific work in the national park is to develop and promote a thorough understanding of the Kruger National Park ecosystems, and to provide high-quality scientific knowledge skills and resources, in order to facilitate and verify rational management of the national park. This is achieved through three main objectives.

To establish inventories of the components of the ecosystem

The inventory work is far advanced and attention is mostly focused on the next step – determining the function and interrelations of these components. However, new species are constantly found, especially among the small life-forms.

To develop an understanding of the functioning and inter-relationships of the components of the ecosystem, including their dynamics in space and time

The Kruger National Park is one of the largest conservation areas on the African continent and comprises about 2 million ha with a very rich biological diversity. To monitor changes in such a system calls for either considerable manpower or very specialized techniques. Researchers have developed innovative techniques, for example, to census animals, monitor vegetation changes and assess water requirements.

To evaluate and study, where necessary, human-induced and natural influences and problems on the ecosystem

The objective is to study and prescribe remedial methods. These are often *ad hoc* projects developed to cope with particular situations. One such study was to find a practical way of vaccinating free-ranging animals. A solution was found, consisting of an aerial (helicopter) method, using discardable dart syringes.

Table 7.1-1: The number of Protected Areas (PAs) in tropical regions and the percentage with species inventories (I) (based on limited field observations, partial surveys of the area, and systematic surveys), together with percentage having comprehensive species inventories (C) (based on systematic surveys only) shown in parentheses (from: Murray et al. 1992; see also Stohlgren et al. 1995).

1. All categories of Protected Area.
2. Including Mexico, Central and South America and Caribbean.

The development of improved monitoring programmes in protected areas is important. However, not only do many protected areas lack monitoring programmes, but many also do not have even basic species inventories. In a study of literature relating to 8 715 protected areas in tropical forest countries, WCMC was able to locate inventories of major taxonomic groups for only 5% of the sites (Table 7.1-1).

7.1.4.3 Threats to protected areas

Many protected areas are under threat. The majority of 135 national parks, in more than 50 countries surveyed in 1982, reported threats of one nature or another (Machilis and Tichnell 1985). More recent surveys show no improvement in the situation, and it is important therefore that such threats to protected areas – and the effects of those threats – be identified and monitored.

7.1.4.4 Use and socio-economic benefits of protected areas

Protected areas provide a range of services and benefits to humans (see Section 13). Important information for the management of these areas is provided by monitoring programmes which address what resources are used,

either consumptively or non-consumptively, and what services are provided. Variables can then be identified and used to monitor both the health of the resource and its value (usually economic or social). One of the easier value variables to monitor is visitation, but it may be necessary to monitor a much wider range of variables to assess more completely the value of protected areas to society.

For example, a report has recently been prepared for the Great Barrier Reef Marine Park Authority which assessed the economic and financial values of the Great Barrier Reef during 1991–2 (Driml 1994). Crudely summarized, tourism is estimated to be worth A\$682 million, commercial fishing A\$128 million, recreational fishing and boating A\$94 million and research A\$19 million, for a total of A\$923 million. This research was extended to cover a number of other areas, and the total value of tourism and recreation in six major protected area complexes was estimated as over A\$1.9 billion. This is clearly a substantial input to the economy of the regions concerned, underlining the importance of understanding the value of these areas (see Section 12). This value is, of course, also augmented by a

range of intangible benefits, such as maintaining local to global processes intact.

The IUCN Commission on National Parks and Protected Areas is currently reviewing mechanisms for assessing and monitoring the true value of protected areas, with the aim of developing a methodology that can be adopted more widely.

7.1.4.5 Inventorying and monitoring outside protected areas

Those natural areas not designated as protected face the pressure of being converted to other land uses such as cash-crop production. A major portion of a nation's forests, for example, are generally earmarked as timber-production areas (Harris 1984). Sound management of these areas requires that an inventory be carried out to ascertain what resources are available and in what quantities, and that the inventory is repeated at regular intervals, for example every ten years, to provide information on sustainable management of the resources. An example of the importance of such resource inventorying and monitoring is shown in Box 7.1-8. Inventorying and monitoring in such national programmes are almost always targeted at timber species, and, in some cases, at non-timber species such as rattans.

The global level of primary productivity to support the present annual yield of fishery resources has been reached (94 million metric tons). It is likely that substantial unmanaged increases in fishery biomass yields will be obtained by fishing down the food web from fishes, causing losses in biodiversity at the species abundance level (Pauly and Christensen 1995). The need for monitoring these changes at the global level in relation to cascade effects throughout the food web of marine ecosystems is recognized as an important contribution to the sustainable management of fisheries (Beddington, 1995).

7.1.5 Summary

- Inventorying and monitoring are used to assess the status of biodiversity and indicate changes at all levels, from genes to ecosystems and landscapes. Such changes can, for example, signal improvements or deterioration in management and sustainable utilization. Species inventories are important in the selection of protected and threatened areas, endemic areas, and ecologically and economically important yet sensitive areas. Modelling of the results of monitoring studies can provide predictions that anticipate species changes with changing environmental conditions.
- Inventorying of biodiversity is the fundamental starting point for its conservation, sustainable use and management. A knowledge of the presence and abundance of organisms in a given area, from local to regional or global scales, is crucial for the

preservation, management and utilization of national and global biotic resources. Inventorying of genes, populations, species, biotopes, ecosystems and landscapes tells us what is there, and, to some extent, their relationships. It also can tell us what is useful and what is threatened.

- Inventorying has an essential spatial component: it tells us where biodiversity is found. This is important for establishing the origins of both harmful and beneficial organisms. Such *beneficials* may be anything from pollinators and biocontrol agents, to potential new crops and medicinal animals, plants, fungi and microorganisms.
- Monitoring is a step beyond inventorying and refers to assessing how, and to what extent, biodiversity *changes* over time. Monitoring is essential for the continued management of biodiversity.
- Monitoring deciphers natural from significant human-induced changes and provides guidelines for managing ecosystems for optimal sustainability. With increasing ecosystem disturbance and landscape fragmentation, it is vital to monitor both short-term changes (days to months) and long-term changes (years to centuries).
- Monitoring of protected areas is crucial for the continual updating of information on the state of the wealth of biodiversity within them. Monitoring of human-utilized areas is also crucial to determine whether that utilization is optimal.

Box 7.1-8: Malaysia: forest resources inventory.

Prior to 1962, no national forest inventory data were available within Peninsular Malaysia. To overcome this lack of essential planning data, the Forest Department initiated a Forest Resources Reconnaissance Survey (FRRS), designed to assess the extent, distribution and nature of the forest resource on all forested lands. This survey was undertaken to provide data, particularly with regard to controlling harvesting of the forests. In 1965, it was expanded to provide additional data on forest resources and development potential as required by the National Land Capability Classification (LCC). Under the FRRS:

- forest lands were classified into broad forest types;
- the distribution and extent of the forest types were recorded;
- the commercial volume of timber per unit area for each type of forest was estimated.

The survey was completed in 1969. It involved the preparation of forest resource maps on an administrative district basis, based on aerial photo interpretation and sufficient quantitative survey on the ground. As a consequence of the ground survey, new tree species were found that were previously not known to occur in Peninsular Malaysia, and tree species were found in places where they were not known to exist before.

The FRRS led to the first national forest inventory of Peninsular Malaysia (1970–2), a project that was supported by the UNDP and FAO as part of the development programme for the forestry and forest industries sector of Malaysia, which consisted primarily of reviewing and complementing the results of the country-wide forest resources survey, with a view to preparing a forest development plan for Peninsular Malaysia. The inventory involved field sampling of main commercial species and species groups in 384 random cluster sample plots laid out throughout Peninsular Malaysia (Anonymous 1973). Each sample, which included 12 separate enumeration plots, totalled 36.4 ha in area. Trees of 305 mm diameter at breast height were enumerated. Mangrove forests were excluded from the survey.

The national forest inventory was repeated in 1981–2 when the most important commercial species of rattan were included in the survey, and again in 1991–2. As part of the development programme for the forestry and forest industries sector of Malaysia, an inventory of the mixed dipterocarp forests of the state of Sarawak on the island of Borneo was carried out between 1969 and 1972 (Anonymous 1974). As with the inventory in Peninsular Malaysia, the main commercial timber species and species groups were enumerated in a total of 503 samples.

Tree flora of Malaysia

The tree flora of Peninsular Malaysia has been documented in four volumes, written by 15 authors and edited by Whitmore (1972, 1973) and Ng (1978, 1989). This work covers over 3000 tree species reaching 90 cm girth, including the gymnosperms and all 99 families of flowering plants with tree species in the region. Herbarium collections at the Forest Research Institute in Malaysia, and at Singapore, were the main source of the studies, with reference to collections in Europe on critical matters.

Throughout the work, keys are based on leaves and twigs as far as possible as these are all that are usually available for identification. The bias towards use in the forest is also shown by the full descriptions of the bole, bark and crown of the living tree, notes on its distribution and ecology, and on its seedlings, saplings, silviculture and economic uses.

Work has started on the tree flora of the Malaysian states of Sabah and Sarawak on the island of Borneo.

Rattan flora of Peninsular Malaysia, Sabah and Sarawak

Based on both herbarium studies and extensive field work, the rattan flora of Malaysia has been documented by Dransfield (1979, 1984, 1992).

7.2 Scales, planning and approaches to inventorying and monitoring

7.2.1 Introduction

How species-rich are the montane forests of Ecuador? How many species of birds inhabit Royal Chitawan National Park in Nepal? To what degree are the trees of the humid lowland forest of Papua New Guinea patchily distributed on a local scale? Can the present species composition of commercial catches support sustainable fisheries within the South China Sea ecosystem? The answers to these questions require the setting of clearly defined goals, the collection of existing and new field data and a statistical framework with which to analyse the information collected. An understanding of the ecological dynamics of the locale or the region then helps to interpret the results. This chapter discusses *approaches* to the inventorying and monitoring of biodiversity, including scales of measurement, project planning and baseline data, at the various levels: genetic, population, species, biotope, landscape and global.

Many techniques and sampling methodologies are currently available for inventorying and monitoring (e.g. UNEP 1986; Goldsmith 1991; Spellerberg 1991; Heyer *et al.* 1994), reflecting the varying nature of organisms, peculiarities of different ecosystems and the diverse approaches of researchers towards the various goals.

When planning inventory and monitoring programmes, it is important to match the method with the precise aim (see

Husch 1978). Existing methods may need to be adapted to the new conditions posed by the problem being addressed. However, although efficiency may be increased by using such particular methods, comparability may be sacrificed. Even if there are no immediate plans to compare results with those from other localities, the use of standard methods will ensure future comparability.

Choice of methods is best made from a problem-solving perspective:

- clearly define the problem, its spatial scale and whether the approach is systematic, ecological or managerial;
- outline the goals – including the needs of both clients and users;
- identify the types of biological information required and the scale and intensity of measurement;
- determine the statistical precision needed;
- be clear on the time needed to achieve the goals, and
- determine whether resources (material, financial and human) are sufficient.

Framed in concrete terms, the types of questions that are asked when developing a monitoring programme may be:

- What is the size and location of the area that is to be sampled?
- Over what time period is it intended to assess biodiversity, e.g. every 1, 5 or 10 years?
- What should be the level of measurement to detect trends? For example, is the aim to detect a 20% change over 5 years, or a 30% change over 2 years?
- What percentage of the time detects significant changes when otherwise there was none (i.e. what will be the alpha level)?
- What percentage of the time detects no population change when in fact there was one (i.e. what will be the beta level)?
- What additional measures of population change should be incorporated (e.g. survivorship, fecundity, turnover)?
- What is the increase in human impact on the system, community or population over the next 1, 5 or 10 years?

One extremely important consideration is the cost-effectiveness of sampling and analysis in inventorying and monitoring (see Margules and Austin 1991). In general, costs increase with the geographical scale of a project, and at the regional or global level (see 7.2.2.1) costs may be one of the most important factors in developing an inventorying or monitoring programme.

7.2.2 Scales of measurement

7.2.2.1 Spatial scale

7.2.2.1.1 Local assessments. All inventorying and monitoring programmes require an acute awareness of spatial scale, which is determined by the question in hand. Local assessments, for example, are usually driven by local needs and resources. The breadth of questions that can be addressed and the number of alternative methodologies that may be deployed often make the design of local assessments difficult and complex. Methods range from compiling simple checklists to comprehensive programmes which track changes in all the major components of local ecosystems. It is therefore critically important to define precisely the scales and goals *before* beginning any undertaking (Samways 1993). Examples of local inventories include sampling within individual biotopes or ecosystems in parks, protected areas, watersheds, lakes, wetlands, agricultural fields and their surrounds, tree plantations, rivers, estuaries and coastlines.

7.2.2.1.2 Regional assessments. Regional assessments include, for example, studies of one or more ecosystems, large river systems, political entities (states, provinces or countries) or continents, ocean basins, seas and large marine ecosystems. Regional inventories may be assembled from analyses of the results of local inventories. At this level, similar constraints to those of global projects may apply. Factors such as the regional infrastructure will be important in defining procedures. For example, in developed nations, the infrastructure of roads and human communities lends itself to inventories being carried out by networks of local workers. In contrast, in developing nations an entire programme, often in remote regions, may have to be conducted by a small centralized staff. This limitation of personnel in tropical and Southern Hemisphere regions, which contain the greater part of all terrestrial biodiversity, is a major limiting factor to biodiversity conservation and utilization. The problems of science capacity and human resources urgently need to be addressed (see Chapter 7.4).

7.2.2.1.3 Global assessments. Global assessments are generally constrained simply by the vastness of the sample area, and as a result the resolution is generally lower than at regional or local levels. A combination of broad-scale and point-sampling methods is used. Broad-scale sampling generally requires the use of remote-sensing methods (see 7.2.10.4) and measures at the levels of the biotope and

landscape, while point-sampling involves measuring a representative selection of localized sampling points. Data from a series of points, when coupled with remote sensing, may provide information that can be extrapolated for global coverage. The limitation is the ability to visit and sample enough points to resolve adequately the global patterns of interest. Information from point sampling is also needed to substantiate data from remote-sensing activities. The point-based method would be appropriate to a programme that depends on an international network of teams, whereas a remote-sensing effort can be carried out by the staff of a single institution based at a central location, with the help of local people familiar with the area.

Other global assessments take a different approach and focus on well-known taxa (see 7.2.9.4), such as birds (ICBP 1992), and plot areas of conservation interest for that group. A goal of some systematists is to use the results of inventorying efforts to compile a global inventory of the species of each group. However, a complete inventory has not yet been achieved for any major group of organisms as new species continue to be found, even for the most well-known groups, such as birds and primates.

7.2.2.2 Temporal scale

The time needed to 'complete' an inventory and how often it will be necessary to conduct monitoring surveys will depend on what is being measured, how the results will be applied, what resources are available to carry out the study, and political and economic stability in the subject area.

Most local inventory efforts are intensive, in that investigators will attempt to assemble as complete a collection of the target species and groups as possible. In contrast, the alternative approach of rapid assessment of species diversity, sometimes using recognizable but unnamed taxa (so-called RTUs), is relatively non-intensive. Such assessments are mostly for immediate conservation or resource management needs or actions (see 7.2.9.3).

Choosing an appropriate time frame over which monitoring will take place is crucial to the success of the exercise. If this is not done there may then be a deficiency of data, making statistical inference difficult and results and management options open to question.

Long-term monitoring, over many years and decades, can provide considerable insight into rhythmic versus stochastic patterns and successional events and will yield a much more complete inventory (e.g. Dallmeier 1992; Owen 1991; Woiwod 1991). The time of year when starting and ending a sampling programme may be crucial, as organisms are responsive to these seasonal changes, even in the tropics (Wolda 1992). It should be clear whether the primary focus of a study is spatial or temporal, or both. Spatial studies may be done at one time of year with intensive comparable sampling. Temporal studies are much

more demanding, in that to be meaningful, they often have to be done over many years (Dempster 1975).

Long-term monitoring is not just about measuring declines in biodiversity. It also has an extremely valuable role in measuring *improvements* in biodiversity conservation, sustainable utilization and human development.

Large-scale experiments, consistent with the size of harvesting methods, are essential as a step towards adaptive management. Testing the response of biodiversity to an array of experimentally produced resource extraction levels, with monitoring of the results, constitutes an alternative to the monitoring of current harvesting techniques. Assessment of experimental results provides a fast way to adaptive management and thus may prevent the further erosion of biodiversity.

7.2.2.3 *Taxon-specific, taxonomically comprehensive and site-based perspectives*

Certain problems require a focus on certain organisms, for example trends in butterfly populations (Pollard and Yates 1993). Other problems relate to the broader assessment of the biodiversity of all organisms within a specific geographical area, their processes and interactions; an example is the ongoing assessment of all organisms living within the Guanacaste Reserve of Costa Rica (see Box 7.2-5).

For both the taxon- and site-based approaches, decisions must be made as to which species will be assessed (see 7.2.8), how biodiversity will be estimated and how these measures will be interpreted (Reid *et al.* 1993).

7.2.3 Project planning

7.2.3.1 *Standardization*

Inventory and monitoring programmes are greatly enhanced when the results can be compared with those from other sites and times. Comparisons improve scientific research and economic planning and allow different organizations to optimize their efforts through shared results, experiences and decisions. The International Union of Forestry Research Organizations (IUFRO), for example, has developed a set of international guides for monitoring forests (Päivinen *et al.* 1994). These guides list minimum data to be recorded in the course of field surveys and remote sensing activities, in order to maximize the sharing of information.

The validity of such evaluations hinges on the use of methodologies that produce comparable data sets, such as those of Majer *et al.* (1994). Besides an inventory or monitoring programme meeting the goals of an individual site, it may also provide meaningful comparisons with other sites through standardization of sampling and analytical techniques. For example, methods used to sample marine turtles in the Pacific Ocean should be equally suitable for sampling those animals in the Atlantic

Ocean. Likewise, point counts of birds in temperate deciduous forests should be the same as those used in tropical forests. Using the same standardized terminology also greatly increases the comparability of the information collected (Banks *et al.* 1987). To date, global standards exist only for the few oceanic taxa that have co-ordinated global projects and the Man and the Biosphere monitoring sites. However, various international groups are now standardizing techniques for measuring and monitoring the diversity of particular groups of organisms, e.g. amphibians (Heyer *et al.* 1994).

Standardization of sampling methods and data analysis can also allow data from diverse studies to be applied to regional and global problems for which they were not originally intended. However, there may have to be a decision, when new technologies become available, whether comparisons over time are still possible using the old and new approaches.

Standard techniques may be difficult to apply because of limited resources. It is essential that the agreed standard methods are appropriate for different levels of resource availability (see Stork 1994). Gadagkar *et al.* (1990), for example, successfully used a range of cheap standardized sampling methods to look at insect diversity in different forest types in India. Some key strategies for inventorying species are outlined in Box 7.2-1.

7.2.3.2 *Validation and calibration*

There is often little information on the accuracy or completeness with which different sampling methods measure biodiversity, particularly for species-rich groups such as insects and microorganisms. Furthermore, there is often uncertainty as to how efficient one method is in comparison with others for particular organisms in different areas or even in the same area at different times. The calibration of such methods is essential if the meaning of the samples taken is to be properly understood (Solbrig 1991; Samways 1994; Hammond 1994). Intensive and long-term studies of sites provide opportunities for the comprehensive testing and calibration of methods. Perhaps the ultimate intensive site study is the All Taxa Biodiversity Inventory (ATBI) proposed by Janzen and Hallwachs (see Box 7.2-5). Until such highly intensive programmes are funded, investigators need to take advantage of more limited opportunities to evaluate particular methods. For example, different methods of measuring woody plant diversity can be evaluated in 50 hectare plots that have been censused completely (Hubbell and Foster 1983; Condit 1995).

7.2.3.3 *Voucher collections and accompanying data*

7.2.3.3.1 *The importance of voucher specimens.*

Vouchers are collections of organisms that are maintained to provide the permanent, physical documentation of

Box 7.2-1: Key strategies for species inventories (*adapted from: Coddington et al. 1991*).

- Use proven collecting methods for different taxonomic groups in order to standardize techniques with previous and future workers.
- Keep the number of collecting methods for each group to the minimum necessary, but maximize the independence among methods.
- Minimize the complexity of sampling: keep ecological area classifications as simple as possible.
- Use general protocols that work in plot-based or plotless sampling.
- Keep the sampling unit general, simple and comparable: time spent sampling is perhaps the best unit of measure.
- The sample unit (e.g. time spent sampling) must be adjusted to permit adequate numbers of species and individuals per species to be collected: sample unit must be small enough to permit among-sample comparisons.
- Large samples should be assembled from smaller replicate samples.
- Data collected should permit variation to be estimated and analysed, especially with respect to site, the individual investigator, time of day, season or year and sampling method.
- Samples of species and individuals per species should be sufficient to construct species abundance distributions that can be used to estimate species diversity.
- Ideally, sampling should be sufficient to produce confidence intervals on estimates.
- Inventory teams should consist of more than one investigator collecting each target taxon.

species identifications and associated data resulting from inventories (Meester 1990; Miller and Nagorsen 1992). Such collections provide the means of verifying previous identifications and validating observations. In short, they provide essential scientific credibility (Miller 1993; Goodman and Lanyon 1994; Miller and Scudder 1994; Cotterill 1995). Voucher collections are particularly important for inventory data where the taxonomy and identifications of the species are uncertain.

Standards for collecting and storing voucher specimens are generally taxon-specific (see, for example, Bridson and Forman 1992, for plants). They relate to the minimum number of specimens required of each sex, age group and morph for each taxon. Specimens preserved as voucher material must meet certain quality requirements in terms of condition and preparation (Herholdt 1990; Escalante-Pliego 1993), and should be housed according to rigid standards of specimen maintenance in designated specimen repositories.

7.2.3.3.2 Important considerations regarding voucher specimens. Investigators should consider collecting voucher specimens for all species except those that are globally or locally threatened or whose collection is prohibited. Although such prohibitions are unquestionably important for protecting desirable and charismatic

organisms that attract both amateur and professional collectors, they can have adverse scientific implications. Blanket prohibitive legislation in some geographical areas poses a serious threat to the gathering of knowledge about biodiversity, as, for example, with dragonflies in Germany, where it is illegal to collect and preserve any specimens (Eislöffel *et al.* 1993).

The rich natural history collections in many temperate and tropical countries are often the result of the serendipitous activities of enthusiastic amateurs. Legislation restricting collecting may threaten the fountainhead of such amateur enthusiasm, particularly in the young of all nations. In cases where collecting is forbidden or facilities are not available, specimens should be documented with photographs or recordings of vocalizations. In some groups of animals (e.g. birds and Orthoptera) vocalizations are important and useful taxonomic characteristics. For example, acoustic recordings were made in France of a bush cricket that is now extinct (Samways 1989). Photographic records are also effective in identifying individual animals in the case of sea mammals, especially whales.

7.2.3.3.3 Essential collecting permits. Where required, *bona fide* collecting permits must be obtained before

making a voucher collection. The collection, acquisition, possession, transport and deposition of specimens of many taxa are regulated either locally, nationally or internationally. Ironically, although habitat loss and landscape degradation, as well as over-exploitation for commercial purposes, are the greatest threats to wildlife, it is scientific collecting that is often most closely regulated. In some cases, however, collecting is a genuine threat, particularly as species become increasingly rare and soar in commercial deadstock value. Such is the case with many butterflies, such as the Corsican swallowtail, *Papilio hospiton* (New and Collins 1991).

7.2.3.4 Statistical analysis

Prior to any biological investigation, it is essential to determine the statistical analyses that will be used to interpret the data. Inventories that require some measure of abundance might employ either qualitative measurement (e.g. rare, common, abundant) or quantitative measurements. Qualitative measures are usually simpler and less rigid but are neither repeatable nor statistically analysable and are therefore rarely suitable for effective monitoring (Morrison and Marcot 1994; Päävinen *et al.* 1994).

Two factors affect the amount of information obtainable from a biodiversity sample: sample size and the amount of variation in the data. Quantitative measures at the interval, rather than nominal or ordinal, level usually require more labour and are data-intensive, but they provide a stronger basis for statistical inference, population and community modelling and prediction. In quantitative biodiversity studies, the statistical sample size is the number of individuals, populations, species, quadrats, cores, nets, biotopes or localities sampled. However, ultimately it is the actual number of individuals of each species that is often the variable of interest. The numbers and kinds of samples are a means of estimating this. In scientific investigations, sample sizes must be large enough to be biologically representative and meaningful. As samples tend to under-record rare taxa, the investigator should obtain a sample that reliably reproduces the population characteristics as distinct from sampling error effects. It is also important to bear in mind the power and robustness, as much as applicability, of the statistical analyses.

Observer bias, which is the distortion that may occur between different observers when individuals are fatigued, ill-trained or unequally experienced, should be avoided. Each observer should have comparable training and any inter-observer differences identified. Biases, particularly to a particular taxon or life stage, also occur when one particular sampling method is used (Southwood 1978). A range of collecting methods, or so-called 'sampling package', may be necessary to sample all the target taxa (Coddington *et al.* 1992; Stork 1994).

A biologically representative sample for most biodiversity

purposes is best achieved through random sampling. A random sample is obtained by an unrestricted process that disposes all individuals in the target population or community the same chance of being sampled. Random techniques avoid biases and increase reliability (see Hayek 1994a, b). This method is acceptable for most biodiversity studies (Hayek 1994a, b). However, random sampling *per se* may miss locally endemic or very rare species, which are often of great conservation interest.

In restricted random sampling, such as stratified or cluster sampling, the target population is divided into relatively homogeneous groups according to factors that influence variability in that population (e.g. sex, habitat and life-history stage). Sampling units (e.g. quadrats, cores, biotopes and microhabitats) from which individuals are sampled, are distributed among those groups. Within each group, however, the individuals are sampled randomly with no restrictions. The purpose of restricting the selection process is to maximize the information obtained while minimizing the cost. Such a procedure is also more likely to capture most of the variations in the sampled area. Usher (1991) and Owen and Rosentreter (1993) provide details on how to design random or stratified random sampling monitoring programmes and also how to avoid the problems of autocorrelation.

Before any new inventory or monitoring programme starts, especially where comparative spatial and temporal data are to be analysed, it is essential to consult some well-tried texts. Possibilities include Elliott (1977); Krebs (1989); Ludwig and Reynolds (1988); Magurran (1988); Soberón and Llorente (1993); Päävinen *et al.* (1994) or Cochran (1977); Lund and Thomas (1989); Schreuder *et al.* (1993) depending on the type of project. It is important, however, to bear in mind that biodiversity management and conservation are not simply about numbers of species and their relative proportions, but also about processes. Statistical analyses really only give numerical credibility to descriptive aspects of biodiversity conservation. Nevertheless, diversity measures and multivariate clustering techniques give a useful classificatory description of an otherwise incomprehensible welter of data. They are a starting point for quantifying biodiversity. It is important, therefore, also to assess qualitative biodiversity, that is the identity of species represented as points in, for example, a rank-abundance curve. Two localities may have equal species richness and evenness, yet one may be home to fairly widespread and eurytopic species, while the other may support many localized, genetically interesting, narrow endemics (Samways 1994; Holloway 1994).

After the initial descriptive data have been analysed, it is then necessary to redefine more precisely the conservation goals and the next steps to be used. For example, experimental verification may be needed (Ludwig and Reynolds, 1988), or aspects of the data then used for

selecting reserve areas (e.g. Spellerberg 1992; Usher 1986) or for initiating a management programme which would then be reassessed in the same or a different way at a later date to see how successful the management has been.

7.2.3.5 Use of existing data

Inventories of biodiversity may be able to make use of existing material (literature, databases, museum specimens) which often document the presence of a species in time and space and may decrease the area or extent of sampling required to document particular aspects of biodiversity. These records also provide a historical perspective, which has important conservation implications in knowing the rate and extent of species increase (especially exotic invasions; e.g. New 1994) or decline (e.g. Marshall and Haes 1988). For example, the decline of freshwater molluscs in Pennsylvania was demonstrable from specimens collected over many decades (NRC 1993). However, existing materials are generally insufficient for complete documentation of the biodiversity of an area or taxon because of the geographic or temporal unevenness of the samples, imprecision of the geographic information and/or incompleteness of information on abundance and habitat. Also, changes in scientific nomenclature and technical terms may occasionally distort the quality of the information generated from these sources. They do, however, permit the identification of gaps in the coverage to which future survey work may be best directed. Lund and Thomas (1995) provide guidance for evaluating existing information for databases.

7.2.4 Baseline data

Baseline data are fundamental units of basic inventory information that are crucial for biodiversity conservation planning and management. They usually include: (1) the presence and/or abundance of species or other units; (2) other dependent biotic data (e.g. plant cover for macroarthropods); (3) the appropriate influential abiotic variables, and (4) human variables. Biotic and abiotic data are the building blocks that make possible meaningful interpretations about spatial and temporal patterns in the distribution of biodiversity and the degree to which these are determined by natural and human-influenced environmental variation. When properly selected and carefully sampled and appropriately statistically analysed (see 7.2.3.4) the data can illustrate patterns of biodiversity.

As the goals and scales of inventorying and monitoring programmes may change with time, the baseline data collected should be sufficiently robust to accommodate such changes. Provided the data represent a robust sample of the system under study, baseline data can calibrate methods of Rapid Biodiversity Assessment (see 7.2.9.3) and, where samples are adequate, can also help evaluate the status of rare and threatened species and levels of

endemism (in Chapter 3.3). Although genetic data are the most discriminating elements of biodiversity, they are of limited use in rapid surveys.

Ideally, baseline data should be relevant across a wide range of environments and should be readily measurable in a repeatable way by different observers. Throughout ecosystems and landscapes, key data will include historical (evolutionary) elements together with those of the present day. In practical terms, the baseline data of most value are those that relate to changes in resources and respond to system perturbation or disturbance (Pimm 1991). Also it is valuable to know which species are resistant to or resilient against such perturbations. Thus, taxonomic and functional biotic data relate to abiotic data such as climate, weather, soil chemistry, pollutants and available nutrients.

7.2.4.1 Biotic data

7.2.4.1.1 Non-taxonomic baseline data. Baseline studies may use of recognizable taxonomic units (RTUs), which may or may not equate to named species but are visibly recognizable as entities. Such RTUs are useful for comparative, localized studies but have distinct disadvantages in biodiversity conservation (see 7.2.9.3, and the discussion by Beattie and Oliver 1994; also Stork 1995). Other rapid means of inventorying an area or biota include the use of functional attributes. Plant functional attributes (PFAs) are readily observable features of vegetation that are considered significant for growth, physiology and survival (for example pollination mechanisms, seed dispersal mechanisms, rooting systems). Certain minimum attribute sets of PFAs (Gillison 1981) can be used in specific combinations to describe individuals in a way that facilitates the detection of within-species variability. While PFAs are independent of species, they provide an additional ecological dimension to taxonomic richness. They represent variation but make no assumptions about 'guild' structures or life-history strategies, which for the most part are poorly known. Ratios of numbers of species to numbers of unique PFA assemblages or *modi* may indicate comparative levels of environmental adaptation across sets of species. While this is a relatively widely accepted and straightforward procedure for plants, it does not seem to be used for animal, fungal or microbial groups.

Other non-taxonomic baseline data include broad vegetation structure, for example mean canopy height, crown cover or projective foliage cover, basal area and visible strata or layers (Päivinen *et al.* 1994). These may be modified by so-called physiognomic attributes such as leaf size or tree buttressing. Often descriptive life forms are recorded, such as trees, shrubs or lianas. Alternatively, very specific life forms, classified according to the position of the perennating organ during the most unfavourable season,

may be used (Raunkiaer 1934; see Section 2.3). This approach may be extended to many finer categories (Mueller-Dombois and Ellenberg 1974) but these are rarely used in practice.

For vegetation, certain life-history categories may be recorded, such as seed dispersal, breeding systems and phenology (such as seasonal flushing of flowers and leaves, or other visible growth rhythms). For animals, non-taxonomic baseline data include feeding guilds and different life-history stages such as larval and adult forms as well as breeding systems. The degree to which these are necessary baseline data for inventory of biodiversity again depends on the scale and purpose.

The species (and sometimes the subspecies or other evolutionarily significant unit (ESU) (Moritz 1994; Vogler and DeSalle 1994)) is the usual currency for baseline studies. But while species richness and abundance can give a useful approximation of the taxonomic characteristics of biodiversity for localities and regions, they do not necessarily permit meaningful ecological comparisons to be made between continents or regions with different taxa. For such scales, higher-order taxonomic ranks (orders, families and genera) may be more appropriate. Even then, comparisons may be misleading, especially where certain genera contain many species and others are monospecific. For this reason, other taxonomically based measures may be used, such as 'taxic' diversity, a measure of taxonomic richness based on the proportion of species per genus (or family). These proportions, particularly when relating to endemic species, have great significance for identifying hotspots of endemism for conservation (Vane-Wright *et al.* 1991; Williams *et al.* 1991).

7.2.4.1.2 Other baseline biotic data. Monitoring at the population or species level may also be directed at variables of the biotope or landscape that are known or assumed to be important to the species of interest rather than at the population itself (Joubert 1983). Such factors can be monitored by a variety of techniques, including remote sensing of the cover types required by a species (Noss 1990). Once there are sufficient long-term data, species, biotopes and landscapes can be modelled so that any change detected in land condition can be used to predict the likely changes in the species. The monitoring of biotope and landscape variables, however, does not obviate the need to monitor populations, as the presence of suitable environmental conditions is no guarantee that the species of interest is present. Populations may vary considerably in density due to biotic factors, while landscape carrying capacity remains constant. Conversely, inferences based only on biotic variables such as population density can be misleading, as for example when concentrations of socially subordinate individuals occur in areas of marginal habitat (Noss 1990).

7.2.4.2 Abiotic data

Animals, plants, fungi and microorganisms are rarely distributed by chance alone. For the most part their distribution in time and space is governed by a set of key environmental factors. Typically these are elements of light (solar radiation), water and nutrients. The importance of these variables typically varies according to the geographical scale. For example, at the global level solar radiation has a major influence, but this decreases with scale to a point where, at a very local level, water and nutrients may dominate or interactions with other living things assume greater significance.

Typical baseline data for inventory purposes include climate variables, especially mean annual rainfall, rainfall seasonality (usually expressed as coefficient of variation or percentage of monthly rainfall), mean annual (screen) temperature (Williams 1987; Unwin and Corbet 1991), minimum temperature of the coldest month, and maximum and minimum temperature. Mist may also play a significant role, especially in upper mountainous regions or in certain desert or semi-arid conditions (Louw and Seely 1982). However, as yet there is no generally accepted method for recording mist interception.

The assessment and monitoring of a range of physical variables may be required for the effective conservation of biological diversity (e.g. Callow and Petts 1992). These factors can illustrate the proximate and ultimate causes behind changes in diversity and can help explain the behaviour of systems, especially when direct measures are difficult to come by.

7.2.4.3 Human-related data

Human population levels and human activities are the causes (and may also be the cure) of many adverse trends in biodiversity. Many human-related variables that both threaten and enhance biodiversity should be taken into consideration during a monitoring programme. Policy-makers are particularly interested in such monitoring programmes because they can identify practices which can be influenced through policy decisions. Human-related variables that may be monitored include:

- The status and trends in human population density (population density has a strong inverse correlation with biodiversity). For example, in the absence of complete and standardized forest inventory data, the United Nations Food and Agriculture Organization used human demographic information to estimate change in global tropical forest over the 1980s (FAO 1995).
- Types of human influence and changes that have influence in specific areas. For example: what are the major sources of pollution (e.g. cities, manufacturing

plants, farming) in the area of interest? What are the pollutants? Is the pollution changing, and, if so, in what way? What is its importance to local or regional biodiversity? What levels and types of pollution are acceptable for the benefit of industry, on the one hand, and natural communities, on the other?

- Extent and trends of infrastructure. For example: opening of new road networks to areas with previous limited human access; highways which create barriers to the dispersal of some plants and animals yet provide roadside habitats for others; dams which inhibit the migration of some animals yet provide new harvesting potential or habitats for others.
- Increasingly intensively managed and/or developed land. For example, trends in deforestation, draining of wetlands, irrigation of arid and semi-arid landscapes, conversion of grasslands to farming or managed pasture systems, conversion of wild forests to plantation systems. Also, improved situations, such as creation of farmland habitat islands for natural enemies of crop pests (Thomas *et al.* 1992), the decrease in spatial use of herbicides to increase biodiversity (Chiverton and Sotherton 1991), and the general use of conservation headlands (Dover 1991).
- Changes in agricultural practices. For example: deeper ploughing, use of fertilizers, pesticides and herbicides, eradication of hedgerows, revegetation of bunds. Yet other aspects may improve biodiversity, such as the planting of hedges, use of conservation headlands and islands in agricultural land and the conversion to traditional meadows of mixed plants in some temperate areas.
- Harvesting pressure exerted on wild resources. For example: overharvesting has caused several fisheries to collapse, yet others that have been sustainably harvested continue to thrive.
- Effectiveness of policies in meeting management goals (good policies and practices may be continued, poor ones discarded and the ineffective refined).
- Socio-political and economic data, such as information on institutional capacity and funding available for conservation, may also be useful in determining conservation needs and in measuring management performance.
- Effectiveness of sustainable utilization of wildlife resources (e.g. Munthali and Mughogo 1992).

7.2.5 Genetic inventorying and monitoring

Loss of genetic diversity is a critical problem, particularly with respect to domesticated organisms (see Sections 2.2 and 3.1) and the potential benefits from bioprospecting (Reid *et al.* 1993) (see Section 13). However, the potential scale for monitoring genetic diversity is vast. Indeed, Annex 1 of the UN Convention on Biological Diversity highlights the importance of the identification and monitoring of described genomes and genes of social, scientific or economic importance (Glowka *et al.* 1994). Reid *et al.* 1993 (Box 7.2-1) identify a number of critical indicators of genetic diversity and domesticated species diversity for management and policy decision-making.

Virtually all problems addressed by genetic surveys involve assaying for genetic variants (or 'markers') and investigating their qualitative and quantitative distribution among individuals within populations or species (Avice 1994). Genetic surveys begin with tissue samples. These may be adjunct to standard inventories and again it is important to have voucher specimens relating to all tissue samples collected. For those studies in which tissues such as blood are obtained from organisms that cannot be collected as vouchers, other means of verifying identity are needed such as photographs, measurements, descriptions or records contained in a zoological botanical institution. An important rider, however, is that it is essential that the museum specimen is biochemically amenable to genetic analysis. For example, selected soft invertebrates should be preserved in 90% ethyl alcohol rather than in formalin.

Many methodologies are now available for assessing genetic variation, and these are discussed in detail in Section 2.2.

7.2.6 Population inventorying and monitoring – some general considerations

7.2.6.1 Population inventorying and monitoring

The general term 'population surveying' has been used, in two ways: (1) in terms of the intrinsic rate of increase, population size at equilibrium and abundance of individuals of different ages and sex at any particular time or place (inventorying); and (2) with reference to the changes over time and space (i.e. dynamics) which includes natality, mortality, immigration, emigration and changes in gene frequencies (monitoring).

The assessment of temporal and spatial differences in these parameters, as well as the biotic or abiotic causes of such differences, can lead to a better understanding of the population dynamics of a species. Thus, population surveys that provide an estimate of demographic parameters may be more informative than those focusing on population size, because they provide insight into the dynamics of the population and allow for the formulation of predictive models.

Both population inventorying and monitoring can be carried out for a limited time over a limited area, or may be applied to many sites, several times, or over a long period. Each monitoring programme, or combination of programmes, will serve different purposes and require a different effort, degree of scientific expertise, time and cost. The techniques applied in a population study will depend on the biological features of the population, the available resources and time, and the questions being asked. The manner in which the basic data are obtained is highly taxon-specific (e.g. for birds see Koskimies and Visnen (1986), Bibby *et al.* (1992); for amphibians see Heyer *et al.* (1994); for plants see Kershaw (1973), Greig-Smith (1983)).

7.2.6.2 Population size and density

It is seldom possible to census an entire population (i.e. to count all individuals directly) and it is often cheaper and preferable to estimate population size from sample data. The density of individuals is estimated over a manageable area and the results extrapolated to a larger area. However, it should be remembered that the dynamics of densities may give misleading impressions of the dynamics of population sizes (Gaston and McArdle 1993). Estimates of population size and density can be either absolute or relative.

Relative estimates provide information on population size or density relative to the unit of sampling effort. Examples include sightings per kilometre walked, counts per day in the field, or individuals per cubic metre of water sampled. Many standard sampling and analytical techniques exist which can be implemented cheaply by well-trained non-professionals (Southwood 1978; Krebs 1989). Such methods are particularly good for surveying or monitoring conspicuous or well-known groups such as birds and butterflies, but it should be noted that relative measures are valuable only in a comparative sense, that is, in comparisons between populations, time periods or species.

Absolute methods are intended to estimate the true number of individuals of a population in a given area of interest at a given time and are often presented as density estimates. Absolute methods provide numbers that are useful in themselves or in comparisons. For plants or sessile animals (if individuals can be distinguished) it is possible in principle to census or to obtain good estimates of density or abundance by straightforward techniques in which one simply marks or records the presence of individuals using a random or stratified sampling design (Kershaw 1973; Greig-Smith 1983). In mobile species, absolute estimates of density often require more sophisticated techniques such as mark-recapture (see 7.2.7.1; Seber 1973; Southwood 1978; Begon 1979; Krebs 1989). Most absolute methods are labour-intensive; for example, recapture of up to 80% or more of the marked organisms may be required to lower standard errors to

acceptable levels. Such methods also require that the investigator be trained in the handling and marking of animals and in the use of the mathematical and statistical techniques associated with the methods.

Another method for estimating density and abundance of populations is 'distance sampling' in the form of line transect, point transect and cue-count data (see Buckland *et al.* 1993; and 7.2.7.4).

7.2.6.3 Population structure and demographic variables

Population size or density is a manifestation of the demographic processes occurring in the population, that is, immigration and births which increase population size and emigration and deaths which decrease it. Data on such demographic parameters thus complement information on population size. Demographic data are most useful if categorized by age, size, sex, genotype, reproductive status, or other relevant variables (Caswell 1989). The assignment of an individual to a category (e.g. genotypes or sex) sometimes involves the use of special techniques. One example of the techniques now available to decipher dynamic demographic parameters among wild populations is skeletochronology, which includes measures of growth rates, age at sexual maturity, cyclicity of growth, etc. (Balinière *et al.* 1992).

Estimates of group-specific fecundity and mortality are fundamental to the understanding and management of populations. Most models of population management include birth rates and death rates (often with variance estimates), as well as population equilibrium values as variables. Immigration and emigration are equivalent to fecundity and mortality when considering the dynamics of a single population. When several populations are being studied, those parameters must be considered separately because of their significance for population viability, metapopulation structure and the potential for inbreeding effects and genetic drift (Caughley 1994) (see Section 4).

7.2.6.4 Population equilibrium

When per capita birth and death rates change with population density, at least within a certain range of density values, population size may reach equilibrium. That is, at some densities, birth and death rates are roughly the same and population size, usually expressed as a density, does not change. The population equilibrium is not a demographic trait in itself, but rather an expression of how the demographic parameters (per capita birth and death rates) respond to factors such as varying resource availability, predator pressure and environmental deterioration.

A measure of population equilibrium is an important tool when managing populations for conservation or for economic purposes (particularly when individuals are introduced to or removed from a region). This state is sometimes equated to the habitat carrying capacity for the

species. It is difficult to determine equilibrium levels from measures of demographic parameters, because estimates of growth rates from several sites or times are required before systematic and significant decrements with density can be detected. Consequently, population equilibrium levels are often estimated empirically as the average population size over a long period.

7.2.6.5 Population analysis

There is a general theoretical framework for the analysis of population status and dynamics and thus analytical tools are fairly standard for many kinds of organisms, provided that data on population size, frequencies of individuals in different categories (e.g. age, size, genotype, sex), as well as category-specific fecundity, mortality and immigration rates, are available. Linear models of population attributes are the most popular analytical tools, but non-linear models tend to be more realistic in the context of population harvesting and management for conservation (Soulé 1987; Getz and Haight 1989; Royama 1992).

To understand population patterns in space and time, estimates of population size and demographic parameters from several sites, or from a single site at different times, can be compared. Studies of population trends require only population size estimates, although sometimes the grouping of data (e.g. into juvenile or reproductive, male or female, etc.) is useful. Providing enough estimates of population size are obtained, population trends can be assessed either descriptively, by plotting the data over time, or formally, using time-series statistical techniques (Royama 1992). A reliable and standardized protocol for estimating population size should be adopted before a survey is initiated (see Pollard and Yates 1993) because modification of a technique over the course of a survey (even if it improves the procedure) makes comparison of the data obtained virtually impossible.

Studies that examine some aspect of population dynamics or provide a basis for the management of a population should measure population parameters several times. If life-table data taken at different times are available, a matrix modelling approach can be used as an analytical tool, either by itself or as part of simulation analyses that take into account environmental stochasticity or different perturbation regimes (Groenendaal *et al.* 1988). Repeated estimation of demographic parameters also allows for the estimation of variances, which are of great theoretical importance (Goodman 1987). However, the field is complex and still in need of a more rigorous mathematical approach.

Two approaches to the study of populations were introduced in Chapter 7.1: the Minimum Viable Population (MVP) and the Population Viability Analysis (PVA). The MVP considers the genetics and dynamics of small populations, with particular attention to the implications of

limited gene pools and demographic stochasticity, for the survival of the species (Soulé 1987; Section 4.2). Determination of the MVP includes factors that are extrinsic to the species such as environmental uncertainty (variability) and natural catastrophes, as well as intrinsic factors such as demographic and genetic uncertainty (Mace and Lande 1991). In large, natural populations environmental uncertainty and natural catastrophes appear to be the most critical factors, whereas in small, natural populations all four factors may be important (Soulé and Kohm 1989).

PVA was developed to consider the complex interaction of factors influencing extinction. It uses population data and growth models (including MVP) to estimate the probability that a population will persist for some designated period (see Section 4.2). PVAs should consider ecological data such as density dependence, spatial structure, low density thresholds, species interactions and mechanisms of ecosystem interactions and should incorporate forecasting methods (Boyce 1992). For example, an environmental perturbation may reduce the population size and induce both detrimental demographic and genetic changes, which in turn can reduce the number of patches occupied by the population. These connections are often hard to evaluate explicitly or to predict. However, a number of models for population persistence have been developed, which seek to integrate these various factors (Mace and Lande 1991; Mace and Stuart 1994). VORTEX (Lacy and Kreeger 1992) is one such model which has been used successfully by the Species Survival Commission's Captive Breeding Specialist Group.

Soulé and Kohm (1989) suggest that an increase in the sophistication of PVA will depend on progress in four major areas relating to the study of population dynamics and persistence:

- the development of an integrated model of population persistence that simultaneously tracks the effects of variation in demographic parameters and in the frequency and amplitude of environmental, catastrophic and genetic variation;
- the expansion of such a model to incorporate geographical structure (i.e. a metapopulation model);
- the examination of the relationship between levels of environmental variability and their impact on the variability of key demographic parameters for a variety of representative species, and
- the examination of the geographical patterns of environmental variability itself.

Target species for MVP analysis or PVA are generally those at immediate risk of extinction, although other

species, including some that are not in danger, could be useful for experimental research and analysis, based on other criteria. Work on such species expands the empirical basis of conservation-orientated population surveys (Boyce 1992). However, it should be remembered that all MVP analyses are based on some model of the population in question and that all models contain some unrealistic assumptions. The researcher must determine the degree to which model assumptions are met in a particular case and devise an improved model where necessary. Mechanical application of published models to other cases is likely to generate faulty conclusions.

With PVA it is important also to be able to model 'catastrophes' and/or model towards a pre-determined range of outcomes and to get a better indication of those factors which are especially sensitive to change, i.e. those factors in which a small change will have a gross effect on the outcomes.

7.2.7 Fauna population inventorying and monitoring – some methods

7.2.7.1 Mark–recapture

This technique is occasionally used for various animals, and is based on capturing a large proportion of the population, marking them, releasing them and recapturing them. This gives only a rough estimate of population size as it requires so many practical, logistical and statistical assumptions (Begon 1979). Nevertheless, the technique has provided some valuable information on populations of butterflies (Pollard and Yates 1993) and birds (Elliot *et al.* 1976; Piper and Schultz 1989). Other mark–recapture techniques such as bird ringing have been extremely useful, principally for establishing migratory routes, but also for monitoring changes in population levels. The Ringing Scheme of the British Trust for Ornithology ringed over 19 million birds between 1909 and 1987, with 400 000 recoveries (Baillie 1991).

7.2.7.2 Radio tracking

A variation on the mark–recapture technique involves the capture of individuals which are then fitted with a small radio transmitter (e.g. on a collar or harness) to allow the species to be radio-tracked. This technique has been used to monitor the movements of large mammal species such as leopard (Smith 1977; Bothma and le Riche 1984) and elephant (Norton and Lawson 1985; Norton and Henley 1987; De Villiers *et al.* 1991) and on some large bird species, particularly threatened raptors such as the Cape Vulture and California Condor (Boshoff *et al.* 1984; Wallace 1993).

7.2.7.3 Remote sensing of populations

Fixed point or ground-based photography is one of the simplest forms of remote sensing (for a full description see

7.4.3.1). Repeated photographs taken from the same point over time allow a species to be monitored in a non-destructive manner. Measurements can be made, for example, of changes in the biomass of a plant species or of the activities at a bird nest or animal den. Shantz and Turner (1958) used repeat ground photography to describe vegetation change in Africa (see also Hoffman 1993).

Aerial photography from kites, balloons and aircraft provides images at relatively low cost with high spatial resolution, high geometric accuracy and good stereo images (Budd 1991). Multi-temporal photographs have, for example, been used very successfully to monitor changes in the density of large woody invasive plant species on the Langeberg mountain range in South Africa (Thompson 1993).

Elephant populations can be monitored by means of low-level aerial photographs (Gwynne and Croze 1980) which, when repeated at regular intervals, can determine the age structure of the population being monitored. This may, in turn, be used to determine the biomass density and health of the population, and as a basis for making deductions about recruitment and population growth. This method is, however, dependent on growth-form curves which have to be obtained from post-mortem studies (Gwynne and Croze 1980).

Yonzon *et al.* (1991) studied the red panda habitat in Nepal. They digitized and overlaid information from maps of land cover, land use, elevation and aspect favourability to give a core habitat map. Then core areas at risk were identified by overlaying a map of land cover and use within 500 m of core habitats. The technique showed that 60% of the core habitat was at risk from human pressure such as grazing and firewood collection.

Inventorying and monitoring vegetation cover is the most practical way of tracking biodiversity at regional and global levels. In the absence of complete geo-referenced species data, we continue to rely on assumptions based on known habitat requirements, historical occurrence data and the current distribution of vegetation types. For example, the 1990 *Countryside Survey of Great Britain* (Barr *et al.* 1993) maps vegetation cover and land use, providing information that can be used to assess change from previous surveys and a baseline from which to monitor future change. Although aerial photography and other remote sensing techniques have been used to survey extensive areas and stratification, the ground survey still provides the most useful data.

7.2.7.4 Territory mapping, point counts and transects

Territory, or spot mapping is useful for estimating the numbers of pairs of birds or animals present in an area during the breeding season without having to capture the species (see Baillie 1991). An excellent example of the use of this technique is the British Common Birds Census which was started in 1962. This census, which is conducted

by volunteers, provides annual indices of the population levels of terrestrial breeding birds in the United Kingdom (Baillie 1991). This monitoring project is also linked to the Nest Record Scheme which has monitored annual changes in bird breeding performance since 1939 (Baillie 1991).

Point counts and transects provide very similar types of information and do not require the capture of individuals. For point counts, individuals of species are counted from fixed points during a specified time interval, whereas for transects observers are required to walk along a particular route recording all the individuals of species on either side of the line walked. Several transect methods have been developed including unlimited distance transects, strip transects, fixed-distance line transects and variable-distance line transects (Baillie 1991). A number of assumptions are built into these techniques (e.g. that all birds on the transect line are detected and that the species does not move away or hide in response to the observer). However, despite these limitations they still provide very useful monitoring data as is shown by various projects to count birds (Järvinen and Väisänen 1975) and butterflies (Pollard 1991; Pollard and Yates 1993).

Since its inception in 1976, the Butterfly Monitoring Scheme has provided information on the changes in numbers of butterflies at well over 100 sites in Britain (Pollard 1991; Pollard and Yates 1993). The information obtained includes the patterns of population fluctuations, the length and timing of flight periods, local distributions and migratory movements. These data have been used by conservation agencies to monitor populations of rare and threatened butterflies and, in some cases, to assess the effectiveness of management measures implemented for their conservation. An unexpected bonus of the monitoring project has been an increased interest in butterflies and their requirements, both by the individuals who monitor them and by conservation organizations. Thus, the very process of monitoring may have contributed to butterfly conservation (Pollard and Yates 1993).

7.2.8 Perspectives and approaches to single-species inventorying and monitoring

When May (1990) wrote, 'without taxonomy to give shape to the bricks, and systematics to tell us how to put them together, the house of biological science is a meaningless jumble', he was making an unequivocal declaration that the identity of species and their relationships is a key to understanding the world around us. That understanding of species then provides a sound basis for biodiversity conservation and management. Species are the unmistakable bricks of biodiversity and yet they have various perspectives that are not easily categorized into a unitary scheme. What follows are some perspectives on species groupings pertinent to biodiversity conservation, utilization and management.

7.2.8.1 High-impact species

Some species have more influence on ecosystems than others. Their impact and abundance may change over time, with other species replacing them in their influential position. Two groups are particularly relevant to biodiversity conservation; keystone species and exotic invasives.

7.2.8.1.1 Keystone species. These play a pivotal role in ecosystems (see Powers and Scott Mills 1995; Box 5.2-1), yet very few have actually been demonstrated in undisturbed ecosystems (but see Paine 1969). Nevertheless, species of palm and fig trees, for example (of about 2000 species in the flora), maintain almost all the vertebrate frugivores in a Peruvian rain forest for three months of the year when other tree species are not in fruit (Soulé and Kohm 1989).

One of the aims of inventorying and monitoring is to identify and assess the dynamic impact of keystone species as ecosystems are altered directly or indirectly by humans. Keystone species need not be harmful but may also be beneficial in modified ecosystems, but this is a field almost devoid of research and is one that needs addressing.

7.2.8.1.2 Exotic invasives. These are newly-appearing species either in natural or human-influenced ecosystems. They may be almost any type of organism which becomes, for example, a new pathogen, vector, weed or invasive animal. Several texts have been devoted to this topic (e.g. Groves and Burdon 1986; Drake *et al.* 1989; Macdonald *et al.* 1989; New 1994; see also Section 11.2).

Monitoring the spread and impact of these invasives is a crucial component of biodiversity conservation. It is estimated, for example, that 900 plant species in the Cape Floristic Kingdom are threatened with extinction, partly as a result of alien tree invasions (Richardson *et al.* 1992). An estimated 1000 additional myrmecochorous plant species in the same region could be threatened if the already established alien ant *Iridomyrex humilis*, which does not bury plant seeds, continues to replace native seed-dispersing ant species (Macdonald 1992). Despite considerable research on invasive biota (see Groves and Burdon 1986; Macdonald *et al.* 1986; Drake *et al.* 1989; di Castri *et al.* 1990), too few studies of successful invaders and related unsuccessful ones have been compared for cogent generalizations to be made about the determinants and effects of success (Soulé and Kohm 1989).

Predictive climatic mapping is proving valuable for predetermining to where a new invasive might spread. Tribe and Richardson (1994) for example (see Figure 7.2-1), used the ecoclimatic program CLIMEX, to determine the possible range expansion of the invasive European wasp, *Vespula germanica*, into South Africa. CLIMEX also proved useful for predicting the spread of various other invertebrate pests (Sutherst *et al.* 1995).

Potentially all ecosystems can suffer the ravages of exotic invasives. The Tasman Sea, for example, is seeing

Figure 7.2-1: The relative suitability of different parts of southern Africa for *Vespsula germanica*. Suitability was assessed by ecoclimatic matching. Crosses indicate localities that are unsuitable for *V. germanica* (Ecoclimatic Index = 0). Increasing suitability is indicated by progressively darker shading. (From: Tribe and Richardson 1994.)

an invasion of the sea-star *Asterias amurensis* (Buttermore *et al.* 1994). Often these invasives can be tramp species circumnavigating the globe. *I. humilis* (from southern South America) and *V. germanica* (from Europe), for example, have not only invaded South Africa but also Australia and New Zealand (New 1994).

7.2.8.2 Indicator species

Certain species flag changes in biotic or abiotic conditions. It is important to inventory these sensitive species because *they themselves* can become the important *monitors*. Which ones are selected depends on the monitoring question being posed. Indicator species reflect the quality and changes in environmental conditions as well as aspects of community composition (details in Soulé and Kohm 1989; Noss 1990; Hawksworth and Richie 1993; Kremen *et al.* 1993; Samways 1994). Species of amphibians, molluscs, birds, chironomid flies, fungi, corals and other marine invertebrates may all be useful indicators. Changes in distributions, abundances and demographic characteristics (e.g. population sex and age structure) of such species may indicate impending adverse changes in an ecosystem as a whole. However, indicator species are often chosen for monitoring simply because they represent

a particular use, ecosystem or management concern (Soulé and Kohm 1989) or are easily sampled, sorted and identified. The need to identify indicators that are appropriate for the task in hand is important and urgent. Also, the species chosen should provide standards of consistency and precision about changes in a community. They must also be reliable enough that changes and trends are unambiguously detected (National Research Council 1993).

Useful attributes of indicator species that are applicable to a wide range of organisms in a variety of ecosystems include (modified from Brown 1991):

- high taxonomic and ecological diversity (many species in each locale or system);
- close association with and identification of the conditions and responses of other species;
- high ecological fidelity;
- relatively high abundance and damped fluctuations (i.e. they are always present and are easy to locate in the field);

- narrow endemism or, if widespread, well differentiated (either locally or regionally);
- well known taxonomy and easy identification;
- good background information (e.g. on genetics, behaviour, biochemistry, ecology, biogeography);
- large random samples encompassing all species variation are possible;
- functional importance within the ecosystem is understood;
- predictable, rapid, sensitive, analysable and linear response to disturbance. Some populations of indicator species, however, may behave spontaneously as a response to an environmental change, for example spiders, locusts and tsetse flies in Africa (e.g. Rogers 1995).
- How many indicator species must be monitored to assess the health of a protected area?
- Which species serve as major mobile links between subsets of species within a community and or between communities? Do non-obvious but important linking species exist?
- Which characteristics of ecosystems are best monitored with indicator species?
- How do keystone and indicator species respond to natural environmental variability and fragmentation and to human-generated environmental variability and fragmentation?
- Can we, in harvested systems, maintain species that depend on the keystone species to provide structural components (e.g. large logs on the forest floor, large standing trees)?

The indicator-species approach has been criticized for its questionable assumptions, methodological deficiencies and sometimes biased application (Landres *et al.* 1988; Noss 1990), but nevertheless it still has great value for monitoring certain changes that take place relative to the specific biodiversity question being asked.

Various authors have discussed the use of indicators to monitor the effects of anthropogenic pollutants on the environment (e.g. Bianchi and Colwell 1986; Kozuharov 1986; Salanki 1986). Pollutants upon entering an environment influence an ecosystem through their effects on various types of organisms, from microbes to higher plants and animals. Generally, pollutants retard growth and reproduction and shorten the life-span of individuals. They also affect the age structure, sex proportions and size of the whole population. Some species decrease in numbers and eventually disappear, while others may become more abundant and expand their ranges. Both responses lead to changes in the structure of the community, which are usually easy to detect and provide valuable signals (National Research Council 1993).

Critical questions regarding the roles and uses of both keystone and indicator species in biodiversity monitoring include (adapted from Soulé and Kohm 1989):

- What are the characteristics of keystone and indicator species?
- What protocols should be used to identify keystone and indicator species for known ecosystems? Can such species be designated objectively?
- How many keystone species occur in different kinds of communities or ecosystems?
- *Sentinels*: sensitive species introduced into atypical conditions as early-warning devices (canaries in coal mines).
- *Detectors*: species occurring naturally in the area of interest which may show measurable responses to environmental change (e.g. changes in age-class, decrease in population size, changes in behaviour). Heathlands are indicators of nutrient-poor acid soils and some vascular plant species may be used as indicators of woodland type.
- *Exploiters*: species whose presence indicates the probability of disturbance or pollution (for example in aquatic habitats, the presence of many tubificid worms and/or red chironomid larvae indicates polluted conditions).
- *Accumulators*: species which accumulate (bioaccumulation) chemicals in their tissues (lichens, woodlice).

Biodiversity indicators are useful for defining and presenting the data that decision-makers require. A minimum set of biodiversity indicators relevant for decision-makers operating at local to global scales is given in Box 7.2-2.

Biological indicators can be used in ecological evaluations, especially for communities indicating areas of conservation interest (Spellerberg 1992). Indicator species are also used in environmental assessments and in the preparation of environmental sensitivity maps. The different kinds of biological indicators can be grouped under the following headings (Spellerberg 1992):

Box 7.2-2: Biodiversity indicators for management and policy decision-making (*from: Reid et al. 1993*).

Wild species' and genetic diversity

- Species richness (number, number per unit area or volume, number per habitat type).
- Species threatened with extinction (number or percentage).
- Species threatened with extirpation (number or percentage).
- Narrowly endemic species (number or percentage).
- Narrowly endemic species threatened with extinction (number or percentage).
- Species risk index.
- Species with stable or increasing populations (number or percentage).
- Species with decreasing populations (number or percentage).
- Threatened species in protected areas (number or percentage).
- Endemic species in protected areas (number or percentage).
- Threatened species in ex situ collections (number or percentage).
- Threatened species with viable ex situ populations (number or percentage).
- Species used by local residents (number or percentage).
- The number of species already lost/extinct from the area.

Community diversity

- Percentage of area dominated by wild species.
- Rate of change from dominance of wild species to domesticated species.
- Percentage of area dominated by wild species occurring in patches greater than 1000 km².
- Percentage of area in strictly protected status.

Domesticated species-diversity

- Accessions of crops and livestock in ex situ storage (number or percentage).
- Accessions of crops regenerated in the past decade (percentage).
- Crops (livestock) grown as a percentage of number 30 years before.
- Varieties of crops/livestock grown as a percentage of number 30 years before.
- Coefficient of kinship or parentage of crops.

- *Bioassay organisms*: selected organisms sometimes used as laboratory reagents to detect the presence and/or concentration of pollutants (some species of trout make suitable bioassay organisms).

Lichens are particularly useful and well documented as bioindicators for a range of environmental pollutants and ecological changes, as listed in Box 7.2-3.

Williams (1993) using terrestrial arthropods, evaluated the effectiveness of restoration of riparian woodlands, and provides an example of monitoring improving conditions (see Figure 7.2-2).

7.2.8.3 Conservation-focus species

As biodiversity conservation is a pragmatic science with a management component, it is important to note those

species that flag conservation efforts. In rough terms, and not exhaustive ones, there are two general categories: umbrella and flagship species, and threatened species.

7.2.8.3.1 Umbrella and flagship species. *Umbrella species* are those whose occupancy area (plants) or home range (animals) are large enough and whose habitat requirements are wide enough that, if they are given a sufficiently large area for their protection, will bring other species under that protection. Many of the world's nature or game reserves were created principally for large mammals or birds and have inadvertently become reserves for other species with smaller ranges, particularly invertebrates (Owen-Smith 1983). Nevertheless, these umbrella species can not be used as an exclusive 'catch-all' for all other species (Prendergast *et al.* 1993). It is important also to note that umbrella species such as

Box 7.2-3: Lichens as bioindicators.

Environmental pollutants

- *Acid rain* (Farmer *et al.* 1992; Gauslaa 1995)
- *Ammonium eutrophication* (de Bakker 1989; Brown 1992)
- *Chlorinated hydrocarbons* (Villeneuve *et al.* 1988)
- *Heavy metal contamination* (Garthy 1993; Lawrey 1993; Gordon *et al.* 1995; Glenn *et al.* 1995)
- *Oil spills* (Brown 1972, 1973)
- *Sulphur dioxide air pollution* (Bisset and Farmer 1994; Hawksworth and MacManus 1989; Hawksworth and Rose 1970)
- *Radionuclides* (Ackay and Kesercioglu 1990; Baeza *et al.* 1994; Benson *et al.* 1983; Biazrov 1994; Rissanen 1992; Steinnes and Njastad 1993)

Climate Change

- *UV radiation* (Fahselt 1993; Galloway 1993; Quilot *et al.* 1994; Wynn-Williams 1994)
- *Water levels* (Gregory 1976; Hale 1984; Wessels and Büdel 1989)

Ecological continuity

- *Deciduous woodland* (Rose 1976, 1992; Etayo-Salazar and Gómez-Bolea 1992)
- *Coniferous forest* (Tibell 1992)
- *Fire* (Eldridge and Bradstock 1994; Wetmore 1983; Wolseley and Aguirre-Hudson 1991; Wolseley *et al.* 1995)
- *Stability of surfaces* (Lawrey 1991; Adamo *et al.* 1993; Sonesson *et al.* 1994)

Further Reading: Henderson (1995); Nash and Wirth (1988); Richardson (1992)

Figure 7.2-2: Over time a restored riparian woodland became more similar to a naturally-occurring riparian reference site in terms of ants in the samples (collections) studied. This illustrates the important role of monitoring improving environmental conditions. (From: Williams 1993.)

cougars, grizzly bears, large cats and pachyderms have already been removed from large areas of their former habitats and may therefore be inappropriate for protecting other species.

Some habitat types may also act as umbrellas and these can be wider than those provided by large vertebrates. In South Africa, for example, the extraordinarily rich plant species in the Cape (The Cape Floral Kingdom) serve as an umbrella for many specialist invertebrates. The relationship between the plants and the invertebrates, however, is not straightforward and highlights the risk of using umbrellas at face value where specialist management may be required (Wright 1993).

Flagship species are popular, charismatic species that serve as symbols and rallying points to stimulate conservation awareness and action. At the larger scale these include animals such as condors, pandas, rhinos, large cats and large primates, while at the smaller scale they include orchids, cacti and invertebrates such as large butterflies and stick insects (Yen 1993). Flagship species may serve as both indicators and/or umbrella species and also provide a highly visible reminder of the progress of a particular conservation management plan.

7.2.8.3.2 Threatened species. Threatened species are species that are rare, often genetically impoverished, of low fecundity, dependent on patchy or unpredictable resources, extremely variable in population density, persecuted, or otherwise prone to extinction in human-dominated landscapes (Terborgh and Winter 1980; Davis *et al.* 1986; Pimm *et al.* 1988; Noss 1990; WCMC 1992; Smith *et al.* 1993). As the number of threatened species increases world-wide, the identification and monitoring of these species has become critical for their conservation. The inherent rarity and ecological characteristics of these species can make them difficult to monitor. There is a vast

literature dealing with this subject and many publications provide case studies and discuss ways to plan and execute monitoring programmes (see Soulé and Wilcox 1980; Morse and Henifin 1981; Synge 1981; Soulé 1986; Palmer 1987; Kesseli 1992; Owen and Rosentreter 1993; Cropper 1993; Given 1994).

The IUCN Red List represents species that are recognized as globally threatened with extinction. The threatened species categories used in the Red List provide the most widely used system for describing the threatened status of species. The current categories have been in place now for nearly 30 years and highlight species under higher extinction risk. These categories have been used increasingly to set priorities for conservation and this change in emphasis has prompted a revision of the category definitions over the past six years (Mace and Stuart 1994). The new IUCN *Red List Categories* (IUCN 1994) require specific approaches to assessing the threatened status of species. They aim to provide an explicit, objective framework that can be applied consistently and widely to classify species according to their extinction risk, to facilitate comparisons across different taxa, to provide a clearer understanding of how species were classified, and to be useful in planning conservation actions. For further discussion of these see Section 13.4.3, especially Box 13.4-2.

The three categories, Critically Endangered, Endangered and Vulnerable are defined on the basis of quantitative criteria that can be applied to any taxonomic unit at or below the species level (Mace and Stuart 1994; IUCN 1994). Meeting any one of the criteria qualifies a taxon for listing at that level of threat. In the absence of high quality data, species may be assigned to categories on the basis of estimates, inference or projection, providing this can be reasonably supported (Mace and Stuart 1994). The categories provide an assessment of the likelihood of extinction under current circumstances. Extinction is seen as a probabilistic or chance process and this listing in higher risk categories implies a higher expectation of extinction. It should be noted that the status of a taxon will depend also on the scale at which it is assessed, whether globally, regionally, or nationally (Mace and Stuart 1994; IUCN 1994). The criteria are most appropriate when applied at the global level and the categorization of a taxon may be different when they are applied at the regional or national level. IUCN is currently drawing up guidelines for the use of national Red List categories (IUCN 1994).

Although the classification of threatened species may be important for identifying areas for protection, there are several disadvantages to using national statistics for monitoring. Most importantly, national statistics respond slowly to changes in the threatened status of species. Furthermore, the signs of national dynamics in threatened species can be ambiguous. For example, if the total number

of threatened species decreases this may indicate either an improvement or a deterioration species may be no longer threatened or they may be extinct!

Similarly, a country with many threatened species may or may not be managing its resources efficiently: is it doing a bad job in protecting its biodiversity because many of its species are threatened or is it doing a good job because it is the last stronghold of so many threatened species?

Threatened species may be inherently rare, that is, they have a low abundance and/or a small range (Gaston 1994), but this does not mean that rare species are necessarily threatened. Species that are naturally rare may be adapted to exploiting a changing environment.

Endemic species are those with restricted distributions (see section 3.3). An endemic species is not necessarily rare or restricted to a small range (Gaston 1994). This is dependent on the area over which endemism is measured. Although plant endemics have been recognized and investigated extensively, less attention has been given to endemic animal taxa (but see Cracraft 1991). Endemic species are, however, increasingly recognized as being an important focus for conservation attention as the threats to narrow-ranged species become more apparent. Furthermore, endemic species are the major components of hot-spots of diversity, and form the basis for selecting priority conservation areas (e.g. Vane-Wright *et al.* 1991; Pearson and Cassola 1992). See section 3.3 for further details on endemic species.

There tends to be a natural bias toward monitoring species already threatened, as emphasized by the large number of *Red Data Books* (RDBs) and the 'Red Lists' (see 7.3.5.5). This approach is neglectful of the many species that are currently common enough not to feature in the 'red books'. Thus there is an essential need to monitor healthy ecosystems so as to keep a check on community structure, especially in view of gradual global changes which may precipitate an unexpected plunge in species richness and abundance. Nevertheless, 'red books' have an important role and the rate of new entries provides an important warning signal.

In their most simple form, *Red Data Books* (Lucas and Synge 1978; IUCN 1990) are simply lists of the elements of our biodiversity that are known to be rare, threatened or declining. They indicate existing or potential losses of species and populations and where appropriate propose remedial conservation action (Ferrar 1989). They also serve an important monitoring function by setting out to answer the general question, 'How are we doing in conserving species?' (Ferrar 1989). At continental and regional scales RDBs often provide the first approximation to the monitoring of biodiversity (Huntley 1988). These RDBs when repeated for a second time provide the first iteration of a monitoring cycle by setting out to compare the changed conservation status of a species after time. This is

often only partially successful as the detail of information in the original lists is often inadequate, and hence changes in the conservation status of a species are often due to the acquisition of more accurate information (Ferrar 1989). Despite this, the mere publication of an RDB leads to critical review and improvement. For example, the 1976 RDB on South African birds was cited in more than 150 papers within eight years of its publication (Huntley 1988).

It is important to distinguish between monitoring for species that are globally threatened, as listed in the WCMC databases, and national *Red Data Books*. As species change categories on the global List they are moving much closer to (or rarely and optimistically, away from) total extinction. *Red Data Books*, on the other hand, are national research and policy documents and often contain species that may be common elsewhere. For example, the field cricket, *Gryllus campestris*, is listed as 'Endangered' in Britain (Shirt 1987) but can be quite common locally in continental Europe.

7.2.8.4 Species with value to humans

A major first step in biodiversity conservation and sustainable utilization is the inventorying of species of direct human value. As this is the essence of biodiversity management in agriculture, horticulture, aquaculture, forestry, veterinary science and medicine, it is covered in considerable detail in Sections 11 and 13. Monitoring these natural species resources is crucial before they are lost forever. Sometimes recently-discovered individuals may be among the last of the species. For example, the bark of the rare tree *Homolanthus nutans*, from the Falealupo Rain Forest Reserve in the Solomon Islands, was recently found to have potentially important anti-viral properties, particularly against Yellow Fever virus.

7.2.8.5 Typical or representative species

One of the most neglected areas of biodiversity conservation is the preservation of once widespread and typical areas. For example, a few hundred years ago the prairie was an extensive and characteristic ecosystem, yet today it is reduced to just a few fragments.

All the above categories of species are 'special' in one way or another. However, biodiversity is about the variety of life in its entirety. In this respect, Usher (1986) makes a strong case for conserving 'typicalness' of species as well as landscapes. In other words, it is important not to forget 'all the other' typical or representative species in a community, besides the 'special' ones (e.g. Eyre and Rushton 1989). This is forcefully brought home when there is a major change in rarity status. The Rocky Mountain grasshopper, for example, went from being an extremely widespread and abundant species to becoming extinct in 30 years (Lockwood and DeBrey 1990). Similarly, the carrion-feeding beetle *Nicrophorus americanus*, once widespread in 32 states of the USA is now endangered and recorded

from only two widely separated localities (Amaral and Morse 1990; Hafernik 1992).

7.2.9 Perspectives and approaches to multi-species inventorying and monitoring

7.2.9.1 Multiple-taxa inventories

Many inventorying efforts target multiple taxa and these have the advantage of providing a broader understanding of the biological diversity of a region. However, such inventories are restricted in their taxonomic scope by the availability of systematic expertise, logistical support or financial resources. In some areas of the world, major inventorying efforts involving numerous taxonomic specialists are increasingly rare, even though they can add substantially to our biological knowledge of those regions. An introductory appraisal of multi-species inventories, at least for invertebrates, is given by Majer (1987).

Nevertheless, there exist areas where the multi-taxa approach has been used successfully for several decades. Methods of making multi-taxa inventories, for example, were developed in soil zoology. The majority of quantitative methods for the extraction of soil invertebrates are based on the separation of different size groups, which occupy different spatial niches in the soil environment: nanofauna, microfauna, mesofauna, macrofauna. Each size group includes different taxa. For example, the nanofauna includes Protozoa, Rotifera and Nematoda; the mesofauna includes Enchytraeidae, Collembola and Acari; and the macrofauna includes Lumbricidae, Myriapoda and Isoptera. Methods of sampling invertebrates migrating along a soil surface also include representatives of many different taxonomic groups (Gilyarov and Striganova 1987).

Characteristic assemblages can be used with geographical data and models to estimate future distributions and areas for conservation. For example, recent inventories in Western Australia have attempted to compare the geographical patterns in species composition of several ecologically very different groups of organisms, including plants, birds, reptiles and land snails. Noting differences, McKenzie *et al.* (1989, 1991) combined the quadrat cross-species records of these groups into a single matrix and then classified each species into sub-sets according to their patterns of congruence in the same quadrats. These sub-sets were analysed separately to derive compositional gradient models (that related to climatic and geomorphic attributes) for reserve system design.

7.2.9.2 Intensive site inventories

Much inventorying is and has been focused at single sites, and as such the resulting faunal and floral lists are valuable tools for ecologists and environmentalists. In spite of this, no single site in the world has ever been fully inventoried. Box 7.2-4 describes the proposed approaches and methods of one All Taxa Biodiversity Inventory (ATBI) (Janzen and

Hallwachs 1994). The ATBI concept has been criticized by some because an inventory that surveys all taxa cannot be undertaken at this time due to the lack of systematic expertise for many groups of organisms, especially the small and cryptic ones. Furthermore, such ATBIs will be time-consuming and expensive, will require extensive input from many experts and may be possible at only a limited number of sites (see Wheeler 1995; Wheeler and Cracraft 1995). Nevertheless, a relatively comprehensive inventory of most of the taxa at a localized study site is feasible in principle and one such effort is now being planned for Costa Rica (see Box 7.2-4).

7.2.9.3 Rapid inventories

Traditionally, inventories have involved relatively intensive sampling, accompanied by the collection of voucher specimens. However, in recent years increased attention has been given to short-term inventories that can provide rapid information on species richness to help set conservation priorities. Rapid biodiversity assessments (RBAs) (Beattie and Oliver 1994) are most commonly applied to site-based problems and seek to inventory a selection of focal taxa to provide a measure of the richness or uniqueness of the site or area. RBAs are commonly undertaken as part of environmental assessments made in anticipation of large-scale development projects. They may also play an ongoing role in conservation assessments when time is short.

RBAs generally use visual encounter surveys (VESs), the assumptions and methods of which are described by Crump and Scott (1994). VESs cannot produce highly accurate estimates of the densities of animals such as birds and mammals unless coupled with a mark-recapture analysis. A further methodological limitation of VES is their inability to sample all biotopes or microhabitats equally. Depending on the goals of the study and the target taxa, the design of a VES may employ random walks, quadrats, patches or transects as the basis for sampling (see Crump and Scott 1994 for details). For some target organisms, 'vouchers' such as tape recordings or photographs can supplement visual recordings.

The primary ingredient in the success of rapid assessments is the employment of field personnel who have a very high degree of expertise with field surveying and identification. Because of their central reliance on visual identifications, rapid assessments involve only those groups of organisms that are relatively well known and easily identifiable in the field, particularly birds, mammals and flowering plants. Rapid methodologies can also be employed to inventory for bioindicators or for local populations of focal species. This might be particularly appropriate for flagship, threatened or large species (for example cats, whales and other marine mammals, primates and some invertebrate groups such as butterflies).

Box 7.2-4: All Taxa Biodiversity Inventory (ATBI) (*from: Janzen and Hallwachs 1994*).

An All Taxa Biodiversity Inventory (ATBI) is a species-level, total inventory (from viruses to big trees) of a large site, which documents:

- which species are present and how to tell them apart;
- where they can be found on the site;
- how to obtain them;
- their natural history (chemistry, behaviour, food, husbandry, population fluctuations, migrations, seasonality, genetics).

All of this information is electronically managed, analysed and displayed in diverse user-tailored formats. The site must be formally conserved and administered, and easily accessible to society.

An ATBI is conducted by national human resources and institutions, with international collaboration. Concurrent with its inventory actions, an ATBI plans and promotes the actual development and use of its wildland biodiversity information products. The goal is to set up wildland biodiversity for many users and many sustainable uses (e.g. education, ecotourism, biodiversity prospecting, agriculture, government planners, scientists, ecosystem managers, conservation managers and environmental monitoring). Of particular interest to biodiversity scientists, an ATBI generates a known universe against which to calibrate a plethora of inventory sampling procedures, a gigantic biodiverse 'miner's canary' with which to monitor the impact of environmental change and the only kind of site in which taxonomy will not be an impediment to studies of interactions.

An ATBI site should be sufficiently large and biologically complex to contain at least half of a nation's or major region's species (hundreds of thousands of species in at least 50 000–100 000 ha (500–1000 km²)). The site should contain many habitats, one or more major ecosystems, a watershed, a major elevation gradient and representative disturbed as well as undisturbed habitats. It must have formal protection status and be accessible to society.

The basic working unit of an ATBI is a Taxonomic Working Group (TWIG) – the set of taxonomists, parataxonomists, technicians and other collaborators responsible for the inventory of a given higher taxon (e.g. nematodes, fungi, Hymenoptera, vertebrates, Coleoptera). As many as 35 TWIGs might be involved in an ATBI. A TWIG contains the in-country biological expertise for a taxon plus a pool of international taxonomists. Each TWIG will determine its own inventory protocols, sampling procedures, stop rules, interim taxonomies and sampling thoroughness within the available time, budget, taxonomic expertise, administration, inter-TWIG interactions, site traits and interactions with biodiversity user groups.

The TWIGs are complemented by groups dedicated to networking through the Internet, in-country science capacity-building, educational outreach, international taxonomic training, development of biodiversity use, and public participation. The process of an ATBI will be strongly influenced by the users of its products as well as its science. The basic information from an ATBI is in the public domain, and the host nation will develop both public and proprietary uses for this information.

The first ATBI will cost as much as US\$100 million, primarily for infrastructure, taxonomy, information management and human resources, with a lesser cost for subsequent ATBIs. Additional resources for post-ATBI specimen and information maintenance and further development will be required to maximize information use. The overall outcome of an ATBI is that conserved wildlands are valued, developed and maintained as a national resource, and that biodiversity understanding moves forward rapidly and locally. An ATBI is an investment of local, national and international scientific, managerial and industrial resources in the non-damaging development of wildland biodiversity.

The government of Costa Rica and the Instituto Nacional de Biodiversidad (INBio) are conducting an ATBI of the 110 000 hectare Guanacaste Conservation Area. This project, termed INBITTA in Spanish and intended to be a pilot project for the tropics, will inventory about 60% of the nation's biodiversity. Its initiation is funded by the INBio, the Norwegian government (NORAD), the US National Science Foundation and the government of Costa Rica. GEF/World Bank funds are sought for the two years of Phase I beginning in 1996. The national ATBI commission contains representatives from those Costa Rican entities that deal extensively with wildland biodiversity.

A rapid methodology is feasible and efficient in that the focal taxa are readily inventoried over a short duration. A second advantage is that they are inexpensive relative to conventional systematic inventories. However, RBAs do not serve as a substitute for scientifically rigorous inventories. The future scientific merit of RBAs is limited in that the reliability of the information collected will often depend on the reputation of the observer rather than on the enduring scientific value associated with voucher specimens that were sampled in a rigorous manner. RBAs are further constrained to sampling only a very small component of the diversity of a region and, because they focus mainly on vertebrates, plants and other readily visible organisms, they may overlook many diverse and unique groups (see Trueman and Cranston 1994). One of the main problems with RBAs is that they say little about important, critical conservation taxa (i.e. the rare phylogenetic, remote, endemic or threatened ones). The interest in a rapid method to identify and inventory priority conservation sites led to the creation of Conservation International's Rapid Assessment Programme (Tangley 1992) and The Nature Conservancy's Rapid Ecological Assessment (Sobrevilla and Bath 1992; Iremonger and Sayer 1994). Box 7.2-5 describes Conservation International's approach to rapid assessments.

7.2.9.4 Global inventories

In many ways, inventories for conservation, environmental impact, or monitoring of change can only be effectively carried out at present using inventory data for a few well-known groups of organisms such as birds and large mammals. As Prendergast *et al.* (1993) and Williams and Gaston (1994) have shown, management decisions based on data for a limited range of organisms of only low or moderate diversity can be misleading. There is, therefore, an urgent need rapidly to increase our knowledge of the world's biota and its distribution. Since, as discussed above, it is not possible at this stage to complete a global

inventory for all organisms, it is essential that a few target taxa are selected for such action. Recent meetings of the directors of Major Entomological Systematic Facilities have agreed such a course of action, with groups such as papilionid and hesperiid butterflies and termites being suggested as the first of a series of focal taxa for the so-called All Biota Taxonomic Inventory (ABTI). The intention is to invest heavily in the inventorying and systematics of these groups so that, with a much more complete understanding of their identities, phylogenetic relationships and distribution, they can be used more in local, regional and global assessments (see Wheeler 1995).

7.2.10 Ecosystem and landscape inventorying and monitoring

7.2.10.1 Monitoring landscapes

Landscapes contain all levels of the biological hierarchy, from ecosystems to species and genes, that are targeted for biodiversity inventories and conservation (Noss and Harris 1986). Landscapes may also include agricultural, forestry, protected and ecologically sensitive areas, which interact considerably (Forman and Godron 1986) and upon which humans have a major influence (Naveh and Lieberman 1990). Inventories of habitats and ecosystems, such as types of forest or large marine ecosystems, can be made at the landscape level. At the regional level, therefore, biodiversity inventories that target landscapes are important as these are composites of alpha, beta and gamma diversities (Noss 1983; see Section 2.3).

7.2.10.2 Monitoring healthy ecosystems

It is sometimes said in casual parlance that ecosystems 'collapse' but this is a dramatization, since ecosystems are continually changing, albeit sometimes in major ways, in response to various types, intensities, and frequencies of disturbance. The disturbance may be natural (Pickett and White 1985) or anthropogenic (see Section 5.3.1). Whatever the cause, any ecosystem may show resistance to

Box 7.2-5: Conservation International's Rapid Assessment Programme.

The interest in a rapid method to identify and inventory priority conservation sites led to the creation of Conservation International's Rapid Assessment Programme (RAP) (Tangley 1992). RAP is a biological inventory programme designed to meet the information needs necessary to catalyse conservation action and give a regional focus to biodiversity protection. The purpose of RAP is to quickly collect, analyse and disseminate information on poorly known areas that are potentially important sites for biodiversity conservation. RAP works by assembling teams of leading field biologists, including host country scientists, to generate preliminary, on-the-ground assessments of the biological value of focal areas. Team members examine an area's biological diversity, its degree of endemism, the uniqueness of its environments and the degree of risk of extinction of its most threatened species.

RAP methodology is designed to provide this critical scientific information quickly and at lower cost than long-term inventory research. This methodology provides a model tool in setting priorities for conservation activity world-wide. It may help also to provide countries with the information and technical assistance needed for the development of national biodiversity strategies.

change (i.e. the impact is too localized or too minor to change the ecosystem) and it may show various degrees of resilience (i.e. ability to return to its former state) (Pimm 1991). Studies of resilience do not ignore natural succession.

Restoration ecology is a major growing field of research and management that is expected to continue to expand in importance (Jordan *et al.* 1987; Soulé 1989). Restoration, however, is a last resort and is far more expensive than maintaining an ecosystem intact in the first place. There must be critical assessment and monitoring of an area to see whether it is simply being 're-greened' or whether an original ecosystem is indeed being reconstituted.

Maintaining a 'healthy' ecosystem does not always mean lack of anthropogenic intervention. Indeed, certain agroecosystems are 'healthy' in the sense that there is maintenance of good soil structure, diversity of soil organisms and minimal impact on surrounding, possibly natural, ecosystems. Monitoring is important in these systems to ensure their continued integrity. The field of restoration ecology is growing rapidly, especially in temperate areas. Monitoring these improvements, especially in the tropics and Southern Hemisphere, is going to be a central feature of biodiversity conservation in years to come (see Figure 7.2-3).

7.2.10.3 Forest inventories

A recent method of inventorying in complex tropical moist forests is through the establishment of large-scale plots. Hubbell and Foster (1983) established a 50 ha plot (1000 m × 500 m) on Barro Colorado Island, Panama, to investigate the organization and dynamics of tropical rain forest. The plot was divided into 20 m × 20 m quadrats that were further subdivided into 5 m × 5 m sub-quadrats, and all woody stems of 1 cm diameter and larger at breast height were tagged, measured for diameter, identified and mapped. The plot is recensused at five-year intervals, and

recruitment into the minimum diameter class, and mortality, are recorded.

A similar 50 ha plot was established in Pasoh Forest Reserve in Peninsular Malaysia (Manokaran *et al.* 1990, 1992) and another is being established in Sarawak, Malaysia. The Pasoh plot provided interesting information: 820 species of woody plants were recorded in the 50 ha plot (Kochummen *et al.* 1990), this being almost one-third of the total number of tree species found in Peninsular Malaysia. See Box 7.1-8 for a more detailed discussion of the Malaysian forest resources inventory.

These large-scale plots, besides providing information on population structures of individual tree species and on tree dynamics, are supporting other studies. For example, population structures of certain palm species are being investigated at Pasoh, and a collaborative project that has just been initiated between British and Malaysian scientists will investigate the diversity of epiphytic plants, the arthropod community, fungi, herbaceous ground flora, and other palm flora in the 50 ha plot. The plot at Barro Colorado Island has been and is supporting such studies as well.

7.2.10.4 Remote sensing

Of the many ways to describe vegetation diversity, the most common are extent, structure, composition, biomass/production, and condition. Each of these can be measured on the ground, but they may be interpreted more effectively from various forms of remote sensing. Maximizing the amount of vegetal information extracted from remote sensing may help to reduce the time spent in the field. We use remote sensing (Lund 1988) to:

- extract direct and indirect information including vegetation type, crown widths, area, vegetation heights, volume, land use, distances between objects, and spectral classes;
- classify and map such things as soils and vegetation;
- co-ordinate and integrate data collection activities by defining areas of responsibilities;
- create sampling frames and sample units;
- navigate to plots and project areas;
- provide sources of information for extrapolating field observations;
- store and document information in the form of annotations on imagery;
- report and analyse results of inventories including inputs to GIS;

Figure 7.2-3: Speculative curves suggesting the intensity of habitat rehabilitation and related activities that might be expected in the future in the temperate zones (upper curve) and tropics (lower curve) (from: Soulé 1989).

- develop bases from which to monitor and update changes, and
- create aids for training, briefings and information transfer.

We use field plots (Päivinan *et al.* 1994) to:

- collect data not available from mapping/monitoring platforms and sensors;
- provide a basis for model building;
- calibrate remote sensing, and
- use in accuracy assessment of remote sensing projects.

Any broad vegetation type that is structurally homogeneous and distinct, such as forest or grassland, is readily inventoried with remote sensing. Using maps and remotely sensed data, with verification from careful ground truthing, it is possible to draw limits around vegetation types, and thus remote sensing can be used successfully to identify the frequency, boundaries, sizes and shapes of various landscape components (Scott *et al.* 1993). Interpretation of the products obtained from aerial photographs or remote sensing requires considerable expertise and manpower, as does the verification of that information by ground truthing. Without adequate ground truthing, however, remotely sensed data can be misleading, because patches smaller than the resolution of the imagery are missed, successional stages are not easily distinguished and gradual ecotones are not perceived (Scott *et al.* 1993). Furthermore, because vegetation in general is a product of the local soil condition, rainfall pattern, temperature and elevation, information on these abiotic factors enhances the predictability of remotely sensed information (Meher-Homji 1971).

When viewed from above, remotely sensed images are like maps spread over a table, with most elements of the landscape clearly drawn. Inventorying the distribution of biodiversity on such a map with appropriate methods is a challenge. Sampling points and grids arrayed across an area have been used effectively for inventorying biodiversity at the landscape level. The number and spacing of points, and the size and array of grids, depend upon the size of the landscape being sampled.

Remote sensing systems may be either passive or active and may be mounted on a flying platform (helicopters, fixed-winged aircraft, satellites) or hand-held and used on the ground. Passive remote sensing systems are those that detect energy that originates from a source away from the sensor. These include aerial photography, multispectral scanners and many satellite-based systems. Active systems

send out a pulse of energy that is reflected back from the target area, examples being synthetic aperture radar and laser altimeters or profilers (see Lund *et al.* in press).

7.2.10.4.1 Passive systems. Passive systems include optical or electro-optical sensors. Optical ‘scanners’ are hand-held cameras and those mounted in aerial or space platforms. Photography taken from the ground, especially from field-plot locations, is useful for documenting conditions on the plot that are difficult to quantify on a form in the field. Vegetation attributes that may be interpreted from ground photography include species composition, structure, biomass and health or condition. Takao (1992) has developed a camera system that can take stereo photographs in a 360 degree circle around the plot centre. From these one can make detailed measurements of the vegetation. Field photos taken from the same location over time provide a good means of monitoring changes in vegetation (Tappan *et al.* 1994). Aerial photography is the most widely used form of optical remote sensing imagery for vegetation surveys. Modern camera systems and films provide imagery of high resolution over a broad range of scales, and record reflected energy in the visible and near infrared portions of the spectrum.

Unlike aerial cameras, electro-optical systems are not limited by the sensitivity of chemical reactions that occur when reflected light strikes the film to create an image. Information from electro-optical systems may be recorded in analogue or digital format. Video systems capture data in analogue form, but most electro-optical systems convert the intensity of incoming energy directly to digital data. Although generally of lower spatial resolution than aerial photography, electro-optical sensor data have advantages for natural resource applications. Image analysts can directly manipulate the digital imagery using computer-based systems to rectify, classify, enhance and display the imagery (Myhre *et al.* 1991; Bobbe *et al.* 1993).

Multispectral or electro-optical systems can be configured to record information from the ultra violet through the visible, near, middle and thermal infra red to the microwave portion of the spectrum. The middle and thermal infrared portions of the spectrum are important for identifying and assessing the condition of vegetation. With some sensors, especially those that operate in the several parts of the spectrum, an indication of the composition and the condition of the vegetation may be obtained. Imagery taken in different seasons can also help in species identification. To determine structure and biomass, we often need high-resolution, stereo remote-sensing coverage. In general, however, the higher the resolution the more costly is the imagery.

Satellite-based systems

Digital imagery from remote sensors carried aboard Earth-orbiting satellites provides information on extensive areas.

Meteorological satellites provide information for specialized natural resource applications. Geo-synchronous satellites provide synoptic low resolution coverage on an hourly basis. Imagery from the Advanced High Resolution Radiometer (AVHRR) carried aboard the United States National Oceanic and Atmospheric Administration (NOAA) series of satellites has been used in assessing forest fuel condition and for developing national vegetation cover maps for several parts of the world. AVHRR imagery has a nominal resolution of 1.1 km at nadir and daily coverage. A 'scene' covers approximately 1750 km \times 6000 km.

Multi-date AVHRR data are valuable for basic mapping, land-cover change detection, and documentation of trends in vegetation conditions over time. The data can be acquired as often as every day and can be used to develop near cloud-free composites based on several consecutive days of imagery. Furthermore, compiled over a one-year interval, these products can be used to identify phenological characteristics of vegetation and would be useful in the development of spectral classifications in monitoring programmes (Giri and Shrestha, in press).

The United States Landsat and French SPOT (Système Probatoire d'Observation de la Terre) satellites provide easily accessible imagery with global coverage. Circling the Earth in near-polar sun-synchronous orbits, the sensors aboard these satellites acquire imagery at a consistent solar time during each daylight pass. Repeat vertical coverage is available from a single Landsat satellite on an approximate 16-day cycle. When multiple satellites in the same series are operating, the orbits are such that the repeat frequency of vertical coverage is proportionally increased.

The current Landsat satellites (4 and 5) carry the Multispectral Scanner (MSS) and the Thematic Mapper (TM). Both instruments are mechanical scanners that employ a rotating mirror to acquire data in the cross-track direction. A full scene of Landsat data is 185 km \times 185 km. The Thematic Mapper has a resolution of 30 m in six bands of reflected energy extending from the blue portion of the spectrum to the middle infrared and an emissive thermal infrared band with a resolution approximately 120 m. Thematic mapper data have been available since 1982. There have been many successful examples of using Landsat TM to help in the mapping of vegetation cover down to forest condition and type. The mapping of old growth vegetation, forest type and structure in the Pacific Northwest Region of the United States is one example (Steffenson and Wilson 1993). Landsat TM has also been used to monitor subtle changes in vegetation such as that reported on the Mark Twain National Forest in the US (Platt *et al.* 1993).

The Multispectral Scanner has a resolution of 80 m in four spectral bands in the green, red and near infrared portions of the spectrum. Multispectral scanner data have been available since 1972. The current Landsat 5 is the last satellite in the series to carry a multispectral scanner

instrument. Although of significantly lower resolution than the Thematic Mapper, MSS data are available for more than 20 years starting in 1972, making the data especially suitable for evaluating landscape change.

The French SPOT satellites carry two High Resolution Visible (HRV) instruments. Unlike the instruments carried aboard the Landsat satellites, the HRVs are solid-state instruments that image the entire swath of the flight path simultaneously. Each of these sensors aboard SPOT 1, 2 (in orbit) and 3 can acquire imagery in the green, red, and near infrared portions of the spectrum. SPOT 4, scheduled for launch in the middle of the decade, will add a mid infrared band to the SPOT HRVs. A full scene of SPOT imagery is 60 km \times 60 km. SPOT multispectral imagery has a resolution of 20 m. The SPOT HRVs can also be programmed to record panchromatic imagery with 10 m resolution. These sensors may be pointed off nadir parallel to the spacecraft ground track, and thus enable the acquisition of additional imagery to previous satellite overpasses and stereo imagery (SPOT Image 1989).

Videography

Videography, especially in the form of airborne video, is a relatively recent addition to the spectrum of remote-sensing systems available for natural resource applications. It uses normal, domestic video cameras and cassettes; the equipment and tapes are inexpensive and no processing is required.

Aerial video is a cheap and effective way of imaging forest conditions for monitoring and measurement activities. Video systems are less sensitive to the problems of exposure common to film camera systems and the resulting imagery is also readily captured for use on computers. Evans (1992) demonstrated the usefulness of global positioning systems (GPS; see Section 9.3) with aerial videography and recommended the use of a gyro-stabilized camera mount to negate the effect of aircraft attitude variations. Bobbe (1992) discusses the use of real-time differential GPS with airborne videography and digitized video data using manual methods. Bobbe *et al.* (1993) discuss similar procedures using a multispectra video camera.

Aerial video can be used for visualization and for detailed analysis of forest attributes (Evans and Beltz 1992). One scheme could employ video as a sampling tool to assess large areas for specific information associated with forest health. This type of survey could be linked directly to information collected at field monitoring plots. Ground plots would be established at a uniform density across all forest lands. These field plots would be located with GPS units, and the GPS co-ordinates for the plots would be used for video mission planning and execution to ensure accurate overflights of the plot locations.

Video imagery would provide inexpensive and fairly detailed information about the canopy structure for field plots and all areas along transects between the plots. Stereo

pairs from video can be used to generate three-dimensional anaglyphs for visualization of canopy characteristics. Digital measurement of information on trees and stands from video may also be possible by use of photogrammetric techniques. Information derived from these analysis techniques can help researchers evaluate current conditions and changes in the forest canopy of field plots over time.

Video systems have lower resolutions than comparable photographic systems and currently lack the calibration necessary for precision photogrammetric applications. They are well suited for many natural resource applications requiring sample or small area coverage. They are also cost-effective for locating features such as isolated groups of insect-damaged trees within a larger survey area. System operators can evaluate video data during acquisition and change mission parameters as necessary. Improvements in camera design and the advent of higher definition recording formats such as Super VHS and HI-8 video have increased the resolution and utility of video systems for natural resource applications. Image analysts can manually interpret video imagery using a high resolution monitor and a playback unit with freeze-frame capability. For enhancement and geo-referencing, the analogue data in individual video frames can be captured as digital data using a video 'frame-grabber'. The relatively low cost of video systems make them a good candidate for many monitoring applications (Myhre *et al.* 1991).

Airborne electro-optical remote sensing systems cover a broad range of capabilities. Airborne systems support working requirements and serve as test beds to evaluate new sensor designs. Nixon *et al.* (1985) showed the utility of multi-band videography to assess vegetal condition and species.

One must recognize that the data from many current airborne digital remote sensing systems are difficult and expensive to register to ground co-ordinates. In addition specialized software and knowledge may be necessary to extract useful information from these data. Nevertheless, airborne systems have an extremely wide range of capabilities and the potential for providing solutions to many unique requirements. Table 7.2-1 provides some comparisons of the use of passive satellite/airborne systems.

Digital cameras

The use of digital cameras is very new in vegetation survey applications. The camera records images on a hard disk integrated with the camera and these are then transferred via an SCSI or parallel connection to the computer or directly to the computer's hard disk by the same connections. Preliminary results by Bobbe *et al.* (1994) indicate that digital camera systems mounted on aerial platforms can provide good quality imagery under a variety of conditions. Digitized photographs from the ground can be used in fractal analysis to help evaluate the health and vigour of the vegetation (Mizoue and Masutani 1993).

7.2.10.4.2 Active systems. Active remote sensing includes radar and lasers. Radar can provide area coverage whereas lasers provide point data.

Radar

A radar system makes use of reflected radio signals, and the all-weather capability of synthetic aperture radar (SAR) systems makes them ideal for use in tropical forest regions with frequent cloud coverage. Radar imagery can be collected from satellite and aircraft platforms. The European Space Agency's ERS-1 remote sensing satellite and the proposed Canadian RADARSAT have view areas of 50×50 km to 500×500 km. RADARSAT will have a resolution of about $25 \text{ m} \times 28 \text{ m}$ and will be useful for monitoring severe changes in forest cover for areas greater than 100 ha. JERS-1, the Japanese Earth Resources Satellite, also has a radar system with similar characteristics and providing global coverage.

Airborne SAR can be used to complement Landsat TM and SPOT for information on geomorphology and vegetation texture, particularly in stereo. It is also useful for detecting changes in vegetation at larger scales (Ahern 1994). Short wavelength radar may penetrate upper vegetation layers potentially to provide information about forest understorey diversity and also about the ground. Some studies have shown that radar data may have utility in forest volume (Wu 1990) and biomass (Dobson *et al.* 1992; Hussin *et al.* 1992) assessments. However, these types of predictive measurements may be dependent on terrain characteristics (van Zyl 1993). Other work has shown that radar imagery could have utility in species group separation (Leckie 1990).

Used in combination with aerial videography and other remote sensor data and ground data, radar has the potential to provide a wealth of information on forest biodiversity. Aerial video and high-resolution radar can supply information at the stand and plot level for detailed characterizations of the forest canopy. Ideally radar systems should be capable of data collection in short wavelengths with the anticipated application of detection of multi-storeyed characteristics within tropical forests. An aerial video system (colour or multi-spectral) could be flown with the radar. This detailed information will be invaluable for forest health or condition monitoring (Brokaw and Mallory 1995).

Lasers

Lasers operate by sending out a short burst of light timed to determine how long the light takes to travel to a target. This time can be converted into distance (Carr 1993). Hand-held lasers have been used to measure distances to trees, from which heights can be calculated. Laser profilers mounted in aircraft can be used to measure heights of vegetation above the terrain (Ritchie and Weltz 1992). When coupled with

Table 7.2–1: Recommended uses for remotely sensed data sources for vegetation (from: Lachowski 1990).

Data Source	AVHRR	Landsat		SPOT		Photography		Video

AVHRR – Advanced High Resolution Radiometer; MSS, MultiSpectral Scanner; TM, Thematic Mapper; SPOT, Système Probatoire d’Observation de la Terre; MS, Multispectral Scanner; PAN, Panchromatic.

Where recommend level of use is:

0 Not recommended for creation of data layer

1 Recommended for small area project where great detail is required (e.g. riparian mapping)

2 Recommended for medium area projects where broader classifications are useful (e.g. district or forest)

3 Recommended for very large area mapping projects where little detail is needed (e.g. state or country).

a Used with terrain data (slope, aspect, elevation)

b Used with field-collected data

c Used with photo-interpretation.

airborne videography and global positioning systems on a sample basis, vegetation structure and biomass can be determined.

7.2.10.5 Monitoring in marine environments and ecosystems

7.2.10.5.1 Introduction. The marine environment is the only uninterrupted, internally moving, three-dimensional environment. Therefore, in principle, every organism can reach all parts of the oceanic environment (Lasserre 1992). As a result, the approach to monitoring both populations and species biodiversity is quite different from that in terrestrial ecosystems. One of the difficulties encountered is that, due to the movement of water, no single observation can be repeated on exactly the same water body.

Ecosystems are generally represented as aggregations of interdependent species living together in communities in response to environmental factors and processes. Quantification of the diversity of ecosystems around the globe is highly dependent on the spatial scale of interest –

there is no single measure of the global diversity of ecological systems. Two standard approaches for characterizing ecological systems are the designation of ‘biogeographic regions’ and ‘ecoregions’. Both approaches consider factors such as the environment, the species composition and the relationships among species. A system of ‘ecoregions of the continents’ is used to demarcate ecologically similar areas of land (ecoregions) in order to predict changing ecological states or conditions. In the oceans, 95% of the annual biomass yields, major losses of habitats, and stresses on biodiversity from overfishing and pollution, occur within 49 large marine ecosystems (see Box 7.2-6). Most coastal countries support the concept of systematic surveys of marine resource species and their environments. However, the utilization of the collections made and the analyses completed are often limited to commercially important ‘target’ species. Augmentation of these efforts with the application of more comprehensive and integrative efforts would provide a valuable contribution to an understanding of the dynamic variability

in biomass yields and the sustainability of biodiversity of species inhabiting coastal ecosystems.

The high-diversity coastal ecosystems contain many pelagic and/or benthic species that range widely over several orders of magnitude in both size and abundance (e.g. whales and picoplankton). Thus the monitoring of these species is logistically a complex problem. Larger species tend to be more mobile, their home ranges are more extensive and individuals can exert considerable control over their location. In contrast, small organisms are unable to control their distribution in space by their behaviour, but in many species their reproductive rates are rapid enough for them to exploit fine-scale events. This gives rise to the problem of discriminating between population responses to coarse-scale events, such as those generated by interannual and decadal variations in climate and those that are caused by shorter term variations induced by ocean weather. The nature of marine organisms is that they change trophic level as they grow. Consideration should be given to sampling the different stages in monitoring surveys aimed at assessing changes in the health of estuaries which serve as nursery grounds for many species. For example, marine reserves such as the Great Barrier Reef in Australia are important conservation areas for a variety of marine biodiversity in contrast to adjacent unmanaged ocean areas (Kelleher 1993).

7.2.10.5.2 Large marine ecosystems. The focus for conservationists monitoring marine organisms has largely been on individual large species such as whales, dolphins, turtles and, to a lesser extent, some of the larger sharks (di Castri *et al.* 1992). However, there have been numerous large-scale, long-term monitoring studies of Large Marine Ecosystems – regions of ocean space encompassing coastal areas from river basins and estuaries on out to the seaward boundary of continental shelves and the seaward margins of coastal current systems (see Box 7.2-6). Although these studies have focused largely on the functioning of the ecosystems, many of the projects have monitored selected marine species, particularly the fluctuations of economically important species in response to over-exploitation and environmental factors (AAAS 1993).

In the Benguela Current Ecosystem, off the southwest coast of Africa, long-term fluctuations in the abundance levels of pilchard, horse-mackerel, hakes, anchovy and other species have been monitored for many years (Crawford *et al.* 1989). In this system the fluctuations are attributed largely to changes in the oceanographic environment, brought about by phenomena such as the El Niño Southern Oscillation (see Lasserre 1992). The effect of the fisheries on changes in species abundance has been found to be secondary (Shelton *et al.* 1985; Crawford *et al.* 1989). Changes in the abundance of species such as pilchards have led to detectable effects in the abundance levels of dependent predator species, particularly marine

bird populations, and to ‘flips’ in species dominance, such as anchovy replacing pilchard (Crawford *et al.* 1989). Similar fluctuations in abundances, and flips in species composition, have been shown in numerous other Large Marine Ecosystems (see Walters 1992). Some of these have also been attributed to environmental changes, while others are attributed to excessive fishing (e.g. off the northeast coast of the USA) and nitrate enrichment resulting from elevated levels of agricultural contaminant inputs from neighbouring landmasses (e.g. in the Baltic Sea).

Changes within these Large Marine Ecosystems are monitored using several standardized and intercalibrated modules, including bottom-trawl surveys for fish and benthos; plankton surveys for indexing biodiversity changes within the water column; acoustic surveys for monitoring pelagic fish; and the use of designated ‘biological indicator’ species for monitoring pollution effects within the ecosystem. These monitoring efforts are augmented by oceanographic measurements and catch records from commercial and recreational fishing efforts.

7.2.10.6 Monitoring freshwater ecosystems

Freshwater ecosystems (FWEs) include lakes, reservoirs and river basins and represent the basic sources of freshwater on Earth. The majority are anthropologically modified by, for example, the building of dams (for energy generation and irrigation purposes), creation of reservoirs, and pollution by industrial and agricultural waste containing heavy metals, oil-hydrocarbons, detergents, phenols, pesticides and other toxicants. Examples of how such additions may affect species in freshwater ecosystems are given in Figure 7.2-4.

Negative changes in hydrological and hydrochemical conditions in FWEs include accidental introductions of non-indigenous freshwater species resulting in decreasing biodiversity and accelerating the extinction of rare and endemic species. The abundance and variability of many species and populations of salmonid and coregonid fishes and the numbers of intra-specific forms of these fishes in Europe have been decreasing. The anadromous sturgeon, *Acipenser sturio*, has disappeared in the basins of the Baltic Sea as have some other species of fishes in European rivers. Populations of acipenserid fishes in Siberian rivers have decreased. The decimation of populations and extinctions of many endemic species of cichlid fishes resulting from the introduction of the Nile perch, *Lates niloticus*, is well known (Barel *et al.* 1985; Witte *et al.* 1992).

Monitoring biodiversity in freshwater ecosystems has been addressed most directly with respect to several kinds of species assemblages. Examples include: the cichlids of the African Great Lakes (especially those of Lake Victoria); the salmonids (including salmonines, coregonines and thymallines) particularly of the Laurentian Great Lakes, the Alpine lakes of Europe and the river–lake–ocean waters of

Box 7.2-6: Global projection of Large Marine Ecosystems

Large Marine Ecosystems (LMEs) are regions of ocean space encompassing coastal areas from river basins and estuaries to the seaward boundary of the continental shelves and seaward margins of coastal current systems. They are relatively large regions, characterized by distinct bathymetry, hydrography, productivity and trophically linked populations (Sherman and Alexander 1986; Sherman *et al.* 1990). In the oceans 95% of the annual biomass yields, major losses of marine habitats and stresses on biodiversity from overfishing and pollution occur inside the 49 LMEs.

Inventorying and monitoring projects are under way in a few LMEs. To meet the objectives of the Global Biodiversity Convention, monitoring and assessment efforts will need to be expanded to encompass all LMEs with special priority given to the most highly productive ones in Asia (e.g. South China Sea, East China Sea) and Africa (Canary Current, Benguela Current, Red Sea and Somalia Current LMEs) where the human population increases of coastal nations are in need of the living resources produced within the LMEs as a source of nutrition. Several of the more developed nations have established time-series programmes to monitor and assess the changing population levels of key resources and environments within LMEs in the Northern Hemisphere. The opportunity for providing technical assistance and capacity-building to the lesser developed countries for implementing, inventorying and monitoring of marine species supporting fisheries in LMEs of the Southern Hemisphere is now being supported by international agencies, including the Global Environmental Facility, the World Bank, UNDP and UNEP, as a contribution to the objectives of the Biodiversity Convention.

Figure 7.2-4: Canonical distribution of species abundances as represented by stream organisms (based on Patrick 1971). The scale for individual/species is an octave (exponential) scale. (a) Probable life conditions for species in a healthy community (based on Cairns 1971). (b) Effect of toxic or oxygen demanding stress on species distribution; U = unstressed, S = stressed. The number of species of moderate abundance is reduced. (c) Effect of moderate fertilization on species distribution; U = unfertilized, F = fertilized. Abundance of many species increases. (From Cairns and Pratt 1993.)

the North Pacific coast; and the darters, or benthic percids, of eastern North American waters. These taxonomically complex families tend to be particularly vulnerable to pollution.

Within such species assemblages, and especially within the salmonids, phenomena at different biodiversity levels interrelate reciprocally and systemically so that the conceptual boundaries between the levels are quite indistinct. Genetically, salmonids are polyploid so that each organism appears to have a redundancy of genetic

information. Populations within species differentiate behaviourally more than they do physiologically or anatomically. Thus, any basis for designating a set of populations as a species depends as much on ethological and ecological criteria as on chemogenetic and physico-anatomical criteria. There are continuing revisions of specific and generic categories and a recognition that rapid changes, as in the salmonid taxonomic complex, do not permit a permanent categorical formalization of the relevant taxonomic criteria.

For further information on monitoring in freshwater ecosystems see Adraanse *et al.* (1994), Callow and Petts (1992), Dumont *et al.* (1994), Jorgensen (1980), Ten Brink *et al.* (1991) and Welcome (1985).

7.2.11 Long-term monitoring of ecosystems

It is essential that long-term monitoring is carried out if we are clearly to identify human-made changes from ‘natural’ changes (Woiwod 1991). The United States National Science Foundation supports long-term ecological research (LTER) sites containing terrestrial, lake, stream and wetland ecosystems. Fifteen of the sites are in the United States, including two in Alaska, two are in Antarctica and one is in Puerto Rico. Each site conducts long-term ecological research which includes biodiversity assessments of selected groups of organisms and extensive associated research on ecosystem ecology (see Box 7.2-7).

The measurement of long-term trends and the establishment of early-warning networks will require continuity of commitment by funding agencies that may be alien to the current fashion for (on average) three-year project time spans.

The value of long-term monitoring is well illustrated by the British Butterfly Monitoring Scheme (Pollard and Yates 1993). Figure 7.2-5, for example, shows that some species such as the dark green fritillary may be declining and therefore more in need of conservation than other species. Unquestionably, long-term monitoring is now an essential requisite in biodiversity conservation, not only to track declines but also to ‘see how we are doing’ with improving environmental conditions.

Long-term research at more than 40 forest plots around the world shows that mature

tropical forests are changing more rapidly now than in the past. The rate of turnover of tropical trees, recruitment into and death from a population, has apparently increased (Phillips and Gentry 1994; Pimm and Sugden 1994). This phenomenon has implications for tropical biodiversity and the global carbon cycle and is discussed in Box 7.2-8.

7.2.12 Summary

- The approaches and methods adopted for inventorying and monitoring depend on the level of

Box 7.2-7: The US Long-Term Ecological Research Sites.

The Long-Term Ecological Research (LTER) programme of the National Science Foundation (NSF) supports a network of 18 research sites in Alaska, Puerto Rico, the Antarctic, and the continental USA. The sites are located on protected areas where continuity of research can be assured. Five are located at US Forest Service experimental stations, and others are on protected land belonging to universities, agricultural research stations, the US Fish and Wildlife Service, the US Bureau of Land Management and private conservation organizations.

Under the LTER programme, the NSF provides research support for scientists working in co-operation with the respective land-managing agencies and organizations. The goal of the programme is to promote long-term, interdisciplinary research. At all LTER sites, species inventories provide a sound taxonomic base for accompanying ecological research. Areas of research include nutrient cycling, plant productivity, population dynamics, and changes in plant distribution as a result of climate change and direct human manipulations. The programme supports a broad spectrum of research projects, from master's scale research to large-scale multidisciplinary, multi-institution projects on landscape ecology and global change. Extensive computer facilities allow electronic communication, data sharing and modelling.

Long-term, interdisciplinary studies provide answers to questions that can be answered no other way. For example, experiments at the Cedar Creek LTER in Minnesota demonstrated the importance of biodiversity on plant production following the major drought of 1988. Areas previously manipulated to contain high plant diversity maintained higher plant production during the drought and recovered more rapidly than did less diverse areas.

In another example, the Sevilleta LTER in New Mexico evaluates the influence of climate dynamics on rodent populations, plant biodiversity and plant production. The studies documented that population increases of the deer mouse (*Peromyscus maniculatus*) were responsible for the recent fatal Hanta virus epidemic in the southwest. Analyses of tissues from mice collected over many years are being used to determine when the new virus became established and to help understand the factors responsible for the epidemic.

Three sites focus on lakes (North Temperate Lakes in Wisconsin, the Arctic Tundra site at Toolik Lake in Alaska and the McMurdo Dry Valley Lakes site in the Taylor Valley, Antarctica). Two sites focus on marine systems (an ice edge marine site at Palmer Station, Alaska and a barrier island site at Virginia Coast Reserve) and 11 sites include some research on streams. At the North Temperate Lakes site, studies of species richness and turnover are under way on the fishes and plankton, as are metapopulation investigations of the zooplankton in a lake district with many adjacent lakes. Since 1975 at the arctic tundra site, physical, chemical and biological measurements have been taken at the deepest station at Toolik Lake at weekly intervals throughout the ice-free period (June, July, August) to monitor for long-term change due to natural or anthropogenic causes.

Across the network, biodiversity studies include surveys and time series on selected groups that allow analyses of species richness and turnover including invasions, extirpation and extinctions. At present, biodiversity studies at the LTER sites are expanding to link with population, community, ecosystem and landscape-level ecological studies. All sites collect long-term data in five core areas; primary production, disturbance, populations and community ecology, biogeochemical cycling and organic matter accumulation. The programme also works to generalize results and analyses at regional levels.

In the next decade, the LTER network plans to broaden its scope to develop multidisciplinary science and public education programmes, develop a multi-agency effort to add sites for wider representation of key biomes and portions of major gradients, create synthesis centres at selected LTER sites and facilitate the advancement of current ecological science and innovative research technologies. The programme has also begun to undertake a major expansion of its international activities, including: assisting in the establishment of networks for long-term ecological research in other countries; creating programmes between US and foreign LTER sites and networks; developing and operating a communication and data sharing system among an international network of sites, and facilitating the establishment of a global system of environmental research sites.

diversity being assessed and the geographical scale of the analysis. It is therefore essential that the goals of a project are clear and relate to the problem being considered. The value of biodiversity findings depends on the relevance and importance of the goals set and the thoroughness of the execution of the

project, as well as its accuracy. The feasibility and accuracy of inventorying and monitoring programmes also depend on the availability of adequate resources. The accurate interpretation of biodiversity information also requires an understanding of the ecological dynamics of the geographical area.

Figure 7.2-5: Fluctuations in abundance of nine butterfly species, 1976–91, based on collated index values from all sites in the British Butterfly Monitoring Scheme. (a) Species with one generation per year. (b) Species with two distinct generations. (c) Species with overlapping generations, given a single annual index. Note the logarithmic scale. (From: Pollard and Yates 1993.)

- Targets for inventorying and monitoring include genes, populations, species, communities, biotopes and ecosystems, particularly those of great scientific interest, those that provide comparisons between areas, keystone species, those that register environmental change, those that are economically important, and those in special need of protection. Variables used to monitor species can be compositional (e.g. abundances, cover values, densities, biomass), structural (e.g. dispersion, range, population structure, biotope variables) or functional (e.g. demographic processes, metapopulation dynamics, population genetics, growth rates).
- Historical collections of organisms provide extremely important baseline information on how a species has changed its range, abundance and form over time. Other existing data may also provide useful historical or even spatially comparative information.
- Species inventories must use standardized methods wherever possible and use recognized sampling protocols that sample the appropriate species adequately but not excessively. This makes the data and the analysis comparable with other studies in other areas. Standardization also allows for later validation and calibration of findings from one time or place to the next. In this respect, sampling protocols and standards such as those produced by Heyer *et al.* (1994) are needed for target taxa. A statistical framework for the analysis of biodiversity information is also essential and should be planned prior to data collection. This then provides meaningful and efficient fact gathering and interpretation.
- Voucher collections are essential for verification of field data and to provide a permanent historical record. In this sense natural history collections are a vital source of baseline data for inventorying and monitoring.
- The methods employed in inventorying and monitoring vary according to the level of biodiversity and the geographical scale of the study, and may include checklists of species, relative abundances, population densities or complete counts of

Box 7.2-8: Increasing turnover in tropical forests: a new threat to biodiversity. (After: Phillips and Gentry 1994.)

Tree turnover in forests is naturally a highly stochastic process. Periods of relative quiescence alternate with pulses of mortality and recruitment as trees fill new gaps. Effective monitoring of turnover rates through time requires long-term observations from many forest plots. Thanks to the cumulative efforts of tropical foresters and ecologists over half a century, tree turnover rates are known from at least 42 mature forest sites.

Plotting these rates against the mid-year of inventory shows that the two are correlated: the more recently inventoried the forest is, the greater its turnover rate (see figure below). However, there is clearly great variation from site to site, and it is possible that ecologists have tended to choose intrinsically more dynamic forests recently. To eliminate this possibility, Phillips and Gentry also analysed all sites that each have at least three successive inventories, allowing a comparison of turnover rates across two different, successive periods. These sites are well distributed geographically (nine in the neotropics, eight in Southeast Asia, two in Africa, and two in Australia). Of these 21 sites, tree turnover rates increased in 17 (i.e. turnover in the second period was greater than in the first), and decreased at only four. Moreover, ranking all sites by the absolute magnitude of change shows that only one decreased substantially (see table below). Non-parametric statistical tests show there is less than 1 in 100 probability of obtaining these results by chance alone. Finally, in eight of nine sites where data on both tree growth rates and tree turnover are known, the relative amount of tree growth increased from the first period to the second. In other words, increased tree turnover is apparently associated with increased productivity.

Tropical forest turnover vs time; 42 sites, Pearson's correlation coefficient $r = 0.443$, $p < 0.01$.

Unfortunately, even the database of sites with at least three inventories is far from ideal. For one, there are still not enough sites monitored closely enough for long enough to quantify the increase in turnover. For another, the sample is not yet large enough to eliminate completely a number of possible confounding local factors. Still, the consistent pattern of increased turnover suggests that regional or global environmental change is a much more likely cause, possibly as an indirect result of human activities. One regional cause may be deforestation adjacent to the sites. Although many of the increasing sites are quite isolated, in other cases deforestation close by may alter local climates and contribute to an increase in tree death. This explanation can be tested where simultaneous datasets on local climatic conditions exist, and where time-series of satellite images are available to gauge regional deforestation. However, there is only one

factor known to be functionally related to plant productivity that is also known to have changed at all sites in concert with the increased turnover: atmospheric CO₂ concentrations. A global tropical forest carbon 'fertilization effect' is an attractive explanation, but a hard one to test directly.

Tropical forests are critical stores of carbon and biodiversity, and increasing turnover is likely to affect both. As trees die and replace each other faster, fast-growing light-demanding trees and vines may gain a relative advantage. Fast-growing plants have less dense wood than slow-growing trees, so mature tropical forests could ultimately act as sources, rather than sinks, of atmospheric carbon. Faster turnover may create more heterogeneous forest environments, and hence actually enhance local species richness. However, larger scale biodiversity levels could decline, with extinctions possible among the slowest growing shade-tolerant tree species and among other life-forms with life cycles tied to these trees.

It is still too early to determine just how important the impact of increasing turnover on biodiversity will be. Because of background spatial and temporal variation in forest structure, detecting even a strong effect on tree species composition will require painstaking identification of new and dying trees over long periods – a tough proposition given the shortage of suitably trained taxonomists. Climbing vines and lianas could be particular beneficiaries in high-turnover forests, yet they are almost universally ignored in permanent plots, so detecting change in the growth, survival or floristic composition of climbers will be very difficult.

However, some common-sense predictions can be made of the impact of increasing turnover on tropical biodiversity. In the short term it should be a minor factor compared to deforestation and the wholesale depletion of top

predators and vertebrate seed dispersers. But in the longer term, by altering the process by which the forest renews itself, increased turnover may threaten many species in the surviving blocks of tropical forest. It is possible that even large areas of forest may be inadequate for biodiversity conservation without simultaneously controlling atmospheric CO₂.

Turnover of trees > 10 cm diameter, in mature tropical forests with three or more inventories; where dyn = mean of measured mortality and recruitment, during *x* (first inventory period), and *y* (second inventory period).

Site	Plot area (ha)	Number of inventories	Timespan (years)	<i>x</i> ; <i>y</i>	<i>dyn_x</i>	<i>dyn_y</i>	ln (<i>dyn_y</i>) – ln (<i>dyn_x</i>)	Rank [absolute change]

Data updated June 1994.

- individuals. Methods should also take into account behavioural, developmental and seasonal variation in abundances. Techniques for monitoring species are highly diverse. Censuses are important for some large and conspicuous organisms, and mark–recapture techniques may be an important means of estimating population size. Similarly, territory mapping, point counts, and transects can be valuable, particularly over a long time-period.

 - Population surveys focus either on population size or on demographic aspects of population structure, the latter being particularly important in understanding how a population is changing in the face of anthropogenic disturbance. There are many methods for estimating population size, and these are chosen according to the organism and level of accuracy required, although none of the methods is entirely satisfactory. Nevertheless, in the case of large mammals fairly accurate estimates of population size over time are often essential for their optimal management. Furthermore, for all organisms an estimation of population size is important for determining rarity or threat status. For very small populations, it is very important that their minimal viable population (MVP) be

estimated, as well as the chances of the population persisting, using population viability analysis (PVA). An important aspect of population monitoring relates to harvestable organisms. Monitoring and modelling determine optimal and sustainable utilization rates. *Red Data Books* and atlases also provide valuable long-term information on changes in rarity status.

- Remote sensing systems have become an important means of monitoring key aspects of vegetation diversity relative both to wildlife and to human populations. Each type of imagery, however, has its own uses, advantages and disadvantages. The large-scale distribution of vegetation can be determined from satellite imagery. Seasonal and multispectral imagery is useful for determining composition and condition of the overstorey. Structure and biomass usually require some height estimates and these can be obtained from stereo imagery, radar or laser profilers. Rapid updates of the condition of small areas can be done with airborne videography or digital cameras. Global positioning units are useful in linking remote sensing and field plots with a Geographic Information System. Remote sensing's quick areal coverage at relatively low cost, may, however, require supplementary information obtained on the ground.
- At the large scale, the marine environment is internally moving and three-dimensional, and presents special monitoring problems. Also at the larger scale, biotopes and ecosystems are inventoried and monitored and such ecological units are sometimes designated a name on the basis of their dominant species. Monitoring of species plays a major role in assessing changes to ecological systems over time, and thus plays a key role in management and biodiversity protection. At the broadest level, biodiversity inventories target landscapes, which are the composites of alpha, beta and gamma diversities. At this level, monitoring biodiversity and its components provides information on land-use dynamics and also on how to manage large marine ecosystems and freshwater systems.
- The inventorying of biota in protected areas, and the monitoring of their status over extended periods of time is very important. Such long-term sites, both inside and outside protected areas, will continue to provide valuable information for biodiversity conservation and management.

7.3 Integrated approaches

7.3.1 Introduction

Informed decisions concerning the implementation of measures to address losses in global biodiversity can only be made on the basis of sound, scientifically based options. Most species data presently available at the population, community, ecosystem and landscape levels are difficult to synthesize because of their spatially fragmented character, lack of comparability and inaccessibility. To overcome these problems, more coherent and integrative species assessments based on standardized intercalibrated temporal and spatial inventorying and monitoring efforts are needed.

Although many countries are attempting to make inventories of their biota, few appear to have cohesive programmes. Often the responsibility for national inventories rests on poorly resourced national museums and herbaria, and on a handful of individuals. Few countries have co-ordinated and planned programmes of action. For many countries the lack of even basic inventory data prevents studies of populations of species and the monitoring of biodiversity at the species level or below. The scale of the task of preparing checklists, systematic revisions and user-friendly keys to the biota is daunting for all but a few of the most species-poor and economically well-resourced countries. Because the task seems so huge and unending, and the economic benefits so vague or apparently non-existent, few governments provide adequate resources. Even in Europe no country has completed a full inventory. Often, which groups have been inventoried will have been determined by the expertise available. For example, although groups such as harvestmen, mutillid wasps, aphids, butterflies and dragonflies have been well inventoried in South Africa, little is known about millipedes, mosses, fungi or protozoa.

It is clear from Section 8 and from previous chapters in this section that the inventorying and monitoring of biological diversity at national, regional and global levels requires substantial systematic and ecological infrastructure, economic input and human resources. Such requirements exceed the capabilities of even the most scientifically advanced nations. Thus, there is a need to share and co-ordinate expertise and capacity, particularly for the inventorying and monitoring of diverse and poorly-known groups such as invertebrates and microorganisms, and to agree priorities for future programmes.

International co-ordination of effort is also essential because the processes and patterns of biodiversity are not restricted by political, social or economic boundaries. Integration is essential if resources (time, money and personnel) are not to be wasted. Without such co-ordination, some areas will be left unresearched and others will be analysed repeatedly using different and incompatible methodologies.

This chapter explores the present state of integration between different programmes for the inventorying and monitoring of biodiversity.

7.3.2 Co-ordinating inventorying efforts

7.3.2.1 Integrated strategies

There have been no attempts to co-ordinate efforts to inventory the world's biota, and some groups of organisms have received a disproportionate amount of attention (May 1988). A much better balance should be sought in the future, and groups such as terrestrial and deep-sea invertebrates and microorganisms should receive much more attention from systematists. Initiatives designed to promote co-ordinated biological studies at the international level, such as the International Biological Programme (IBP) (1962–72), have helped to create a baseline understanding of natural systems. In particular, the IBP introduced the mathematics of systems analysis into ecology, to help make sense of the complex functioning of natural systems and the dynamics of biodiversity (Worthington, in UNESCO 1993). However, this initiative and others such as The World Conservation Strategy (1976–77) and the Sustainable Biosphere Initiative (1991), failed to address directly the problems of inventorying and monitoring.

Agenda 21 calls for inventorying and monitoring programmes to be incorporated into most of the international conventions (e.g. Biodiversity, Global Climate Change, Deforestation, Desertification). Given the increasing demands for information, and reductions in research budgets, we must start to integrate and co-ordinate our inventorying and monitoring programmes. Lund (1986) and Lund and Wigton (in press) provide guidance on designing integrated inventories.

7.3.2.1.1 National efforts. Most nations have established inventory programmes for forests, soils and agricultural lands. Some of these involve the use of permanent plots for monitoring change. For example, natural forest inventories have been carried out at regular intervals in Malaysia, in collaboration with FAO, to obtain information that would allow for an orderly development of the forest industry (see Box 7.1-8). Some nations, including the Sudan (Obeid and Hassan 1992), Ethiopia (Mamo *et al.* 1994), Uganda (Drichi 1994; Hedberg 1994), Senegal (Gueye 1993) and Tanzania (Mgeni 1990), have initiated multiple resource inventories across several landscapes (e.g. forested, agricultural and range lands). Such surveys, with very minor modifications, can provide estimates of change in vegetation biodiversity.

In Sudan, for example, the reforestation and anti-desertification project (SRAAD) was established to reverse the processes of desertification and declining soil productivity which have led to a reduction of agricultural production and income of traditional farmers

in Western Sudan. A pilot multi-agency effort was launched in November 1989, through USAID and the Government of Sudan, and was completed in February 1990. Advanced technologies such as Landsat imagery, global positioning systems and geographic information systems (GIS) were used in conjunction with traditional resource inventory and mapping techniques. Products included image base maps at scales of 1:100 000 and 1:250 000, vegetation type maps, and multiple resource inventory and socio-economic data entered into GIS. Data were collected with the aim of meeting local, national and global needs (Anon. 1990; Lund *et al.* 1991; Obeid and Hassan 1992).

In the last few decades several countries, including Australia and Canada, have made major advances in their biotic inventories, and more recently, countries such as the USA, Mexico and Costa Rica have commenced national inventory programmes. The National Biological Survey of the USA (now the National Biological Service) (NRC 1993), established in 1993, is responsible for the co-ordination of inventorying and monitoring of biodiversity for the USA. Other agencies of the USA government are also supporting national inventorying of biota. The US Department of Agriculture Forest Service and the National Resources Conservation Service (formerly the Soil Conservation Service) have been monitoring the forests and agricultural lands of the USA since the 1930s. In the southern region of the country, data sets are available that represent a baseline of plots revisited during five surveys made over the past 60 years. The information is used to assess changes in the timber resources and associated biota of the region (Rudis 1991). The national inventory of forests includes an estimated 400 000 one acre field plots and 6.5 million photographic plots across the landscape (Lund *et al.* in press).

Arguably the most impressive advances have taken place in Mexico and Costa Rica through the formation of CONABIO and INBio, respectively (see Boxes 7.3-1 and 7.3-2). The approaches taken by these two countries are different, reflecting their different scientific and cultural heritages. Both approaches are built on the skills and enterprise of local peoples. However, as in almost all national efforts they are still dependent, to some degree, on expertise from other nations. Costa Rica, for example, has few taxonomists and is reliant on the collaboration of overseas scientists. Indeed, one of the major drawbacks of these national approaches is they can all too easily stretch the international pool of specialists. If there is just one world authority on a particular group of fungi, for example, then it may be a full-time job for several years for that person to work just on the relevant group of fungi in Costa Rica. This would mean that there may be no available expert for this group for any other part of the world.

7.3.2.1.2 International efforts
DIVERSITAS

At the international level, one initiative to promote co-operation in the inventorizing and monitoring of biodiversity is included as part of the DIVERSITAS programme of IUBS, SCOPE and UNESCO (di Castri and Younès 1991; di Castri *et al.* 1992a, b). This programme, launched in 1991, arose out of the recognition that a conceptual framework and direction was badly needed for the rapidly growing numbers of studies on biodiversity.

DIVERSITAS has four main themes, including the inventorizing and monitoring of overall biodiversity, and the genetic diversity of wild relatives of cultivated species. This programme covers all levels of biological diversity, from genes to ecosystems, incorporating both marine and terrestrial systems and involving a variety of scientific disciplines – genetics, physiology, population biology, ecology and taxonomy (Solbrig 1991; di Castri *et al.* 1992a). It is currently under review. In practice, no agenda for inventorizing has yet resulted from DIVERSITAS, although several important actions have been taken. The

original concept of inventorizing and monitoring (Coddington *et al.* 1991; di Castri *et al.* 1992a, b) proposed that a few sites be very *intensively* studied for all organisms and that at a larger number of sites a range of selected target taxa be more *extensively* inventoried. DIVERSITAS promoted the use of the UNESCO Man and the Biosphere Reserve network (see below) as the focal sites for inventory programmes since inventory studies have either been carried out or are in progress at many of them. The *intensive* theme has since been expanded by Janzen and Hallwachs (1994) as the All Taxa Biological Inventory (Box 7.2-4).

Several countries, such as Brazil, Russia, China, Japan, France and the USA, have started their own DIVERSITAS activities (Longino 1994; Barbault 1994; Zhao 1994; Sokolov *et al.* 1994) but the work plans of these different programmes have not yet been co-ordinated.

One of the greatest problems for inventorizing is the lack of adequate local, regional and international resources for systematics. Two recent initiatives, Systematics Agenda 2000 and BioNET-International (discussed below), seek to address these problems.

Box 7.3-1: Mexico's CONABIO.

In March 1992, the Mexican National Commission for the Knowledge and Use of Biodiversity (CONABIO) was created by the Mexican Government. Its mission is to promote and co-ordinate the biodiversity efforts performed by many Mexican universities, research centres, NGOs and government agencies. CONABIO has a mandate to advance the inventory of the Mexican biota. This long-term task must begin with a compilation of the information that is held in museums and herbaria, and this has been initiated by supporting projects for the computerization and networking of national museum collections, by agreeing with foreign museums on the repatriation of information on Mexican specimens, and by field work in selected areas. CONABIO now holds 80 databases with more than half a Gygabyte of georeferenced data from the labels attached to specimens collected in Mexico. The information covers vertebrates, invertebrates and plants. A very significant part of these databases comes from more than 40 foreign museums and herbaria. CONABIO follows closely the model of the Australian ERIN (Environmental Resources Information Network) regarding custodianship of the data by the original sources. As agreements with the source institutions proceed, information will be added to the Gopher (WWW homepage is under construction) maintained by CONABIO.

This information, together with maps and socioeconomic data, is being organized in a single information system, which will be the factual basis of the Biodiversity Strategy that Mexico, as a signatory of the Convention on Biological Diversity, must complete. CONABIO intends to use the information to support both academic and research activities and to advise government agencies and NGOs in matters relating to monitoring, ecological planning, restoration activities, evaluation of environmental impact assessments and so on. To do this most of the data held must be made available to the public, requiring an agreed set of policies from the suppliers of the information regarding access, copyright, costs, acknowledgements, updating and so on.

CONABIO is also supporting projects on the training of parataxonomists (an adaptation of the pioneer experience of INBio), the sustained use of tropical species (butterflies, hardwoods, resins), the eradication of invading species, and public awareness. Over its almost three years of existence, 770 project proposals have been submitted to CONABIO. Through a process of external peer review nearly 200 have been selected for support. Most of CONABIO's funds come from donations of the Federal Government to a private fund which channels resources to the selected projects. The Mexican Government has committed an annual budget of about US \$6 million to CONABIO's fund. About 15% of these resources are spent in administration and the rest in projects.

As an advisory body, CONABIO has participated in the assessment of environmental impact studies, in the negotiation of contracts between pharmaceutical companies and Mexican universities and indigenous groups, and in multinational negotiations.

Box 7.3-2: Costa Rica's national biodiversity institute (INBio).

Created in 1989, INBio is a non-governmental non-profit institution dedicated to the conservation of wildland biodiversity through facilitating its non-destructive intellectual and economic uses by national and international society (Reid *et al.* 1993). It is focused on biodiversity inventory, prospecting, information management and information dissemination. INBio's activities are largely concentrated in Costa Rica's National System of Conservation Areas, a network of government-owned parks and protected areas that covers 25% of the country and contains an estimated 500 000 species (Sittenfeld and Elmez 1992; Sittenfeld and Villers 1993). INBio's national inventory and biodiversity prospecting are well under way for plants and insects, and rapidly broadening to other taxa (see Box 7.2-4, ATBI and the Guanacaste Conservation Area, Costa Rica).

The inventory is conducted in large part by parataxonomists, explicitly trained lay paraprofessionals who bring specimens and other information to INBio from their biodiversity offices in or near the Conservation Areas (Wille 1993; Janzen *et al.* 1993). The field work of the parataxonomists is guided by the INBio inventory managers, who do taxonomy in co-ordination with national and international taxonomic specialists. Reference collections, field guides and electronic identification services are being established. Detailed information on species ranges and natural histories is accumulating rapidly. Information on identities, distributions and natural history is being put in the public domain through Internet and publications. The local abilities at inventory and information management developed through the INBio process are being shared with other tropical countries through on-site workshops. Collaborative agreements for biodiversity inventorying have been developed between INBio and various tropical countries and biodiversity institutions.

INBio's biodiversity prospecting programme seeks out potential users of biodiversity and facilitates the contracted flow of Costa Rican wildland biodiversity research samples and information to the commercial research and development process. The returns contribute to the management income for the conserved wildlands and may eventually make a serious contribution to Costa Rica's economy (Reid *et al.* 1993). The current focus of biodiversity prospecting is on discovery of chemicals from plants, insects and microorganisms for use in the pharmaceutical and medical industries. However, expansion is envisaged in other areas, including organisms as sources of genes for biotechnology, biological control and pesticides. These aims are illustrated by two successive two-year contracts between INBio and the pharmaceutical company Merck & Co. to prospect for biologically active compounds from a limited number of plants, insects and other organisms. The samples, collected by INBio within the government-owned Conservation Areas, are managed under agreement with the Ministry of Natural Resources, Energy and Mines (MIRENEM) and processed in INBio's laboratory. Merck & Co. paid INBio US \$1.3 million for each contract, in return for sample collection, identification, data management, and personnel training: 10% of these funds (and 50% of any royalties) go to MIRENEM for classical conservation, while the remainder is spent on biodiversity development at INBio and in the Conservation Areas. A similar five-year contract is now in progress between INBio, Cornell University and Bristol Meyers Squibb. Wild organisms discovered to have domestic potential then become new crops and livestock (e.g. Coghlan 1994).

BioNET International

BioNET-International was initiated by the inter-governmental CAB-International in 1993 to help generate biosystematic self-reliance in the developing world (Jones and Cook 1993). BioNET aims to mobilize and pool existing biosystematic resources within developing countries and to increase and sustain these through the transfer of skills, knowledge, scientific expertise and other resources from developed country institutions.

BioNET is envisaged as a series of interlinked, sub-regional Technical Co-operation Networks in developing countries (known as Locally Organized and Operated Partnerships or LOOPS), supported by a consortium of expert institutions from developed countries (BIOCON) and a central technical secretariat (TECSEC) (Jones and Cook 1993). BioNET originally had particular concern for arthropods, nematodes and microorganisms (Jones and

Cook 1993), but has since expanded to include other invertebrates (Jones 1994). Other groups may be included in the future depending upon regional needs (Jones and Cook 1993). Four priority areas have been identified for the initial focus of the LOOPS:

- information and communication services;
- training of personnel;
- rehabilitation of collections and the establishment of new resources, and
- the development and application of new resources.

In June 1994, the first LOOP was established in Europe (EuroLOOP). This group currently includes 60 institutions

representing 22 countries, including three international institutes based in Europe. The first sub-regional LOOP, an association of seven Caribbean states known as CARINET, was formed in December 1993. Each member country has its own National Co-ordinating Institute and from these a Network Co-ordinating Institute has been chosen to coordinate the LOOP. It is expected that four other LOOPS in East Africa (EAFRINET), Southeast Asia (ASEANET), the South Pacific (PACINET) and Southern Africa (SAFRINET) will be developed in the near future (Jones and Cook 1993, 1995).

Systematics Agenda 2000: Charting the Biosphere

Systematics Agenda 2000: Charting the Biosphere (SA2000) is a programme of discovery and research proposed by a consortium of three international societies of systematic biologists; the American Society of Plant Taxonomists, the Society of Systematic Biologists and the Willi Hennig Society, in co-operation with the Association for Systematic Collections (SA2000 1994a, b). This ambitious scientific initiative aims to document and synthesize knowledge about global species diversity within the next two to three decades.

The first mission of SA2000 (Box 7.3-3) recognizes that current efforts to inventory global biological resources are inadequate. Its five priority goals are designed to increase our overall knowledge of global species diversity and to expand systematic information about groups of organisms that are particularly important for society. Missions 2 and 3 (Box 7.3-3) recognize the need for better information on the phylogenetic relationships of important species groups and an efficient system for information storage and retrieval so that this information may be utilized more productively. Expected benefits from SA2000 include:

- an increased number of usable species resources;
- an improved database to help conservationists and biological resource managers preserve as well as utilize their nations' species diversity;
- knowledge to guide the selection of new and improved food crops and medicines, and
- baseline data for monitoring global climate and ecosystem change, rates of species extinction, ecosystem degradation and the spread of exotic, disease-causing and pest organisms.

SA2000 has proposed a co-ordinated action plan to increase training in systematics, to help countries establish the capacity to survey and inventory their biological diversity, and to build collection-based infrastructures including museums, herbaria, and repositories for microorganisms and genetic resources. The action plan focuses on six main initiatives (SA2000 1994b):

- establishing and enhancing systematic research centres housing collections in all countries committed to understanding, preserving and using their biodiversity;
- supporting institutions that educate systematists and train support staff;
- expanding the number of research positions in basic and applied systematics;
- developing co-operative international research and educational links among systematic institutions world-wide;
- creating electronic communication linkages among these same institutions, with outreach to society, and
- supporting comparative systematic research that is taxon-based and world-wide in scope.

SA2000 recognizes the need for national, scientific systematic research centres, such as CONABIO (Mexico) and INBio (Costa Rica) (Boxes 7.3-1 and 7.3-2), staffed by professional systematists with taxon-based expertise. Some may be built on existing centres, while others will be newly created. Each centre will also require a collection of organisms. To prevent duplication of collections or expertise, SA2000 suggests that systematists with a global knowledge of particular taxa be funded through international centres to conduct research at sites around the world. Co-operative research, database linkages and partnerships between institutions are regarded as essential.

IOPI and SPECIES 2000

Co-operation to produce products of wide utility to biosystematics and biodiversity studies is also reflected by the International Organization for Plant Information (IOPI), established in 1991, which aims to produce a checklist of the world's vascular plant species through a co-ordinated effort involving numerous specialists and institutions. This augurs well for the SPECIES 2000 Global Master Species Database programme adopted by the IUBS 25th General Assembly in September 1994, the detailed planning for which is in progress with CODATA.

MARBID

Within 49 Large Marine Ecosystems (LMEs) (see 7.2.10.5.2) world-wide populations and communities of fish, plankton, marine mammals and birds are being monitored by coastal nations. The principal focus is on fish communities as renewable living resources contributing substantially to the nutritional needs and economies of coastal countries. In the recognition that fish surveys are now conducted systematically throughout the extent of

Box 7.3-3: The missions and goals of Systematics Agenda 2000 (From: Systematics Agenda 2000. 1994a, b).

Mission 1: To discover, describe and inventory global species diversity

- to survey marine, terrestrial and freshwater ecosystems to achieve a comprehensive knowledge of global species diversity;
- to determine the geographic and temporal distributions of these species;
- to discover, describe and inventory species living in threatened and endangered ecosystems;
- to target groups critical for maintaining the integrity and function of the world's ecosystems, for improving human health and for increasing the world's food supply, and
- to target the least-known groups of organisms.

Mission 2: To analyse and synthesize the information derived from this global discovery effort into a predictive classification system that reflects the history of life

- to determine the phylogenetic relationships among the major groups of organisms, thus providing a conceptual framework for basic and applied biology;
- to discover the phylogenetic relationships of groups of species that are critical for applied biology, targeting species that are important for human health and food production, as well as for conservation of the world's ecosystems;
- to discover the phylogenetic relationships of groups of species that are of critical importance for the basic biological sciences, such as those having broad relevance for experimental science and those critical for maintaining the integrity and function of ecosystems, and
- to develop more powerful techniques and methods for systematic data analysis.

Mission 3: To organize the information derived from this global programme into an efficiently retrievable form that best meets the needs of science and society

- to develop systematic, biogeographic and ecological databases of species information based on species housed in the world's natural history collections;
- to integrate data from specimens housed in systematic collections with information contained in GIS databases, thus providing a means to monitor past and present effects of global change on species distributions and extinction;
- to develop linkages among databases for the efficient retrieval of all available information about species and the places in which they occur;
- to develop and implement an information system that can be accessed efficiently by a broad international user community;
- to develop data dictionaries of taxonomic names, geographic localities and other information basic to all systematics databases;
- to develop data products, including guides, keys, electronic floras and faunas and monographic works, and
- to develop mechanisms for maintaining and updating databases and information networks including continuing hardware and software support.

many of the LMEs, the US National Marine Fisheries Service (NMFS) has initiated a Marine Biodiversity Database (MARBD). The NMFS has large numbers of databases on the distribution of species based on fish surveys conducted during the past 120 years, and information on species has been computerized for data collected during the past 30 years. These databases include information on marine and estuarine organisms from a large number of taxonomic groupings (e.g. fish, plankton, benthos, birds, mammals), and are linked to a newly developed system of visual outputs of distribution and abundance patterns designed to provide managers of marine resources with readily usable information to aid in the implementation of resource sustainable practices (Collette and Vecchione 1995; Mickevich 1995).

CENPLANK

The Centre for Plankton Collection, Sorting and Identification (CENPLANK) of Szczecin and Gdynia, Poland, is an international project that has been in continuous operation for the past two decades. The objective of the project is focused on long-term changes in the states of coastal marine ecosystems using plankton as a means of inventorying and understanding variability in the species biodiversity and abundance levels of ichthyoplankton (fish eggs and larvae) and zooplankton components of large marine ecosystems. Countries participating in the project are the United States, Poland, Canada and the United Kingdom. On an annual basis, an average of 5000 plankton samples are collected from the Gulf of Alaska, East Bering Sea, California Current, Gulf of Mexico, the Southeastern US Coast, Northeastern US Coast and Baltic Sea. They are sorted to species, enumerated and entered into an extensive marine ecosystem data archive. The samples are collected from research vessels, and vessels of opportunity within the spatial extent of several of the large marine ecosystems, using plankton nets of varying sizes. Continuous plankton recorder systems are deployed in collaboration with the Sir Alister Hardy Foundation for Ocean Studies in Plymouth, UK. The project has processed 80 000 plankton samples and has in its archives one of the most extensive enumerations of plankton biodiversity in the world. In 1995, the project is entering its twenty-first year of plankton sample collection, identification, archiving and analysis (Ejsymont and Dutkiewicz 1994).

7.3.3 Co-ordinating monitoring of biodiversity

Monitoring change in biodiversity is almost non-existent for many countries and rarely is it linked to programmes for inventorying biodiversity. The exceptions to these are annual bird counts and sometimes vegetation surveys for a few countries. One of the most comprehensive programmes for monitoring is that in the UK (Box 7.3-4), although even here the range of taxa involved is rather small. In many

ways monitoring of biodiversity is more co-ordinated and advanced in the marine area because of the lack of clear national boundaries. Several important collaborative initiatives in both terrestrial and marine systems are considered below.

7.3.3.1 Vegetation cover and land use

7.3.3.1.1 The Food and Agriculture Organization of the United Nations. The 1990 Forest Resources Assessment (FRA 1990) of the FAO presents a global analysis of the distribution of forest ecosystems in 1990, as well as changes during 1980–90. The study was conducted for three separate regions: temperate forests in developed countries (UN-ECE/FAO 1993), tropical forests in developing countries and non-tropical forests of developing countries (FAO 1993). The resolution at which this analysis was undertaken also permits the analysis of the extent and change of forest cover at the sub-national and national levels.

The FRA 1990 assessment of the tropical zone was made using two complementary approaches. The first was based on a statistical analysis of existing, reliable forest inventory data from different countries. The output consists of country-by-country results in a standardized format for the reference years 1980 and 1990, a database including all source information (FORIS) and a model for producing the standard results. The second approach made use of multi-date observations of forest cover using high resolution satellite images for 1980 and 1990 at statistically chosen sample locations. The survey covered 10% of the tropics.

The remaining studies, covering temperate forests in the developed countries and non-tropical forests in the developing countries, are based solely on the compilation of national forestry statistics. This introduces problems of data comparability due to differences in the base years inventoried from country to country and in the methods and definitions used. In order to overcome some of these problems and to standardize national-level data to two base years (1980 and 1990), the assessment of tropical forests incorporated demographic evolution and ecological zoning to model forest cover change (FAO 1993).

All three regional studies are limited by the accuracy of the underlying national data used. Data availability, timeliness and quality varied considerably from country to country (WRI 1994; and see below). To model cause and effect of deforestation, FRA 1990 compiled three geo referenced data-sets for the tropical countries depicting (1) the forest extent around 1980 using available national maps, (2) eco-floristic zones, and (3) sub-national boundaries with time series of population data. The World Conservation Monitoring Centre has also put together maps of tropical moist forest distribution based on a variety of national and sub-regional forest cover and vegetation maps. However, many of these are outdated or of questionable

Box 7.3-4: A summary of the extent of terrestrial biodiversity monitoring in the UK (From: the Biodiversity UK Biodiversity Action Plan. Anonymous 1994; Note: All figures are approximate).

Total coverage

Institute of Terrestrial Ecology (ITE) Land Cover Map	25 land cover types
ITE Biological Records Centre schemes	5 000 taxa
British Trust for Ornithology (BTO) <i>Breeding Bird Atlas</i>	250 taxa
BTO <i>Wintering Bird Atlas</i>	200 taxa
<i>British Lichen Society Atlas</i>	750 taxa

Sample coverage

Department of the Environment (DOE)/ITE Land use/Countryside Survey	90 508 1 km squares
Northern Ireland Countryside Survey	620 25 ha squares
Bristol University Badger Survey	2 700 1 km squares
Botanical Society of the British Isles (BSBI) Monitoring Scheme	350 10 km sq/1000 tetrads
BTO Key Squares Survey	350 10 km sq/1000 tetrads

Regional

Phase I Habitat Survey	89 surveys
National Parks	10 parks
Environmentally Sensitive Areas	19 ESAs

Site-based

Environmental Change Network	9 sites
Butterfly Monitoring Scheme	100 sites
Constant Effort Sites	90 sites
Rothamsted Insect Survey (Moths)	70 sites
Rothamsted Insect Survey (Aphids)	24 sites
Joint Nature Conservation Committee (JNCC) Seabird Monitoring Programme	150 sites
Common Bird Census	250 sites
Waterways Bird Survey	100 sites
National Bat Colony Survey	350 sites
Wintering Wildfowl and Waders	50 taxa
Nest Record Scheme	30 000 nests
De Montford University, Amphibian Survey	150 sites
JNCC Invertebrate Site Register	10 000 sites
National Otter Surveys	7000 sites
Red and Grey Squirrels in State Forests	1000 10 km squares
Rare Plants in Great Britain	300 taxa
Rare Breeding Birds Panel	100 taxa

quality (Hammond *et al.* 1993). No map exists for the temperate forests of the world.

Subject to availability of funds FAO now intends, in co-operation with other interested organizations, to assess forest cover on an annual basis, combining a 10% sampling scheme with coarse resolution wall-to-wall remotely sensed imagery and to build up a spatially referenced picture of tropical forest cover for the world (Singh pers. comm.).

Within the framework of the FRA, a systematic review was made of the current national capacity for monitoring forest change. The findings can be summarized as follows:

- There is considerable variation among regions (see Table 7.3-1) with respect to completeness and quality of information, with Asia faring better than tropical America and the latter being better than tropical Africa.
- There is considerable variation in the timeliness of the information. On average, the data are ten years old, which is a potential source of bias in the assessment of change!
- Some countries have carried out more than one assessment. However, these countries have not used

appropriate techniques, such as Continuous Forest Inventory (CFI) design, for the assessment of change.

- Only a few countries have reliable estimates of actual plantations, harvest and utilization, although such estimates are essential for national forestry planning and policy-making.
- No country has carried out a national forest inventory containing information that can be used to generate reliable estimates of the total woody biomass or biodiversity.
- It is unlikely that the state and change information on forest cover area, biomass and biodiversity could be made available on a statistically reliable basis at the regional or global level within the next 10 or 20 years, unless a concerted effort is made to enhance the country capacity in forest inventory and monitoring.

These findings establish that forest resource assessments are among the most neglected aspects of forest resource management, conservation and development in the tropics. For the follow-up of FRA 1990, the most important requirements are (1) continuation of the FRA 1990 sampling approach to provide deforestation trends, and (2) extension of the sampling to cover all the forests of the world, both tropical and temperate, in developing and developed countries. It has been the main finding of the FAO global report, currently in preparation, that information on change produced from national statistics is not adequate to meet the needs of policy-makers and scientists.

Several other organizations are using remote sensing techniques to map forest or land cover digitally at global or regional levels. These include the International Geosphere Biosphere Programme (IGBP), the US Geological Survey (global land cover), the Commission of the European Community's TREES project (tropical moist forests), NASA's PATHFINDER programme (wall-to-wall map of tropical moist forests on three dates), FAO's AFRICOVER project (Africa, land cover) and The Woods Hole Research Center (South American land cover) (ENRIC 1994; Bied-Charreton (in press); Stone *et al.* 1994). With the exception of the South America map, these projects are either ongoing or at the planning stages. Mapping land cover at the national level is more advanced. A number of countries, for example India, Thailand, Indonesia and Brazil, are using high resolution imagery to inventory and monitor changes in their national land cover (WRI 1994).

The PATHFINDER project covers only the tropical moist forests with high resolution satellite data. The classification is simple, including forest and non-forest as

the main categories. The TREES, IGBP, US Geological Survey and Woods Hole efforts rely on low resolution (AVHRR) imagery. This lacks the accuracy of high resolution imagery (for example it is difficult to distinguish forests from certain crop types or to look at fragmentation except at the coarsest level). None of these projects will distinguish between the various classes of forest transitions essential for assessing levels of biodiversity losses. Supplementary ground information is an essential component as satellite imagery can not be used to derive detailed data on vegetation phenology, or to distinguish accurately between natural and plantation forests and between degraded and undegraded areas. Information of this sort will not be available through any of the mapping efforts listed above. As of August 1994, FAO's sampling efforts excepted, no data are forthcoming that will give either a statistically reliable estimate of the world's remaining forests and other vegetation types or how quickly natural vegetation is being converted, fragmented and otherwise degraded, regionally or globally.

7.3.3.1.2 CORINE. The CoORDination of INformation on the Environment system, CORINE, was set up in 1985 to gather, co-ordinate and improve the consistency of information on the state of the environment in the European Communities. This aim is being achieved through the development of 'procedures for the collection, standardization and exchange of data in the community, as well as the establishment of a geographical information system, to provide policy-related information on the community environment' (CEC 1989). CORINE uses the ARC/INFO GIS programme and is held jointly in Birkbeck College, London, and the Directorate General for the Environment in Brussels. The system contains a geographic base including information on coastlines, national boundaries, administrative regions, water patterns, slopes and settlements. Projects for which data are being gathered include water quality, air, biotopes, coastal erosion, land cover, marine environments, soil erosion, water resources and land quality.

As part of the biotopes project, an inventory has been set up within the CORINE system of all the sites considered worthy of conservation at the community level on the basis of their floral and faunal characteristics. The criteria for site selection include the presence of vulnerable species of plants or animals, the presence of vulnerable habitats, the richness of the site for a particular taxonomic group and the richness of the site for a syntaxon of phytosociological units. The information is currently only in a provisional state and the data vary in their consistency and completeness. Recently, attention has been drawn to the fact that the vegetation classification used by CORINE ignores some important habitats. In Britain these include hay meadows, water meadows, snowbeds and sea lochs, and as a consequence these areas may lose their protected

Table 7.3-1: State of forest inventory and monitoring capacity in the tropics at the end of 1990
(Source: FORIS database of the FAO 1990 Forest Resources Assessment Project.)

Region	Number of countries under assessment	Number of countries with forest resources data at national level							
		Forest area information (number of assessments and reference years)				Other data recorded			
		No assessment	One assessment		More than one assessment	Forest conservation and management	Forest plantations	Volume and biomass	Forest harvesting and utilization
			before 1981	1981–1990					
Africa	40	3	23	12	2	4	8	2	4
Asia and Pacific	17	0	1	6	10	10	8	7	7
Latin America and Caribbean	33	0	15	9	9	11	8	9	4
Total	90	3	39	27	21	25	24	18	15

status by the European Union’s new Habitats Directive (Pearce 1995). However, around 5 200 registered sites are currently contained within the CORINE database and these are expected to increase to between 8 000 and 9 000 in the future. Some of these sites already have protected status but others do not. CORINE also holds information on designated areas – sites that are recognized by national legislation as being under formal protection for the purpose of nature conservation. To date this includes about 12 000 sites but again the number is expected to change as existing data are validated and new information becomes available.

The CORINE system also holds mapped information on the distribution of vegetation types at a scale of 1:3 million. This map was published in 1988 and recognizes over 100 vegetation classes. However, it depicts only climax and plagioclimax vegetation, not the actual existing vegetation types (CEC 1989). In addition, the system keeps data on soils, climate (including rainfall, temperature humidity and snow cover), air (atmospheric emissions and air quality), water (freshwater quality and bathing water quality) and socio economic data (including air traffic and nuclear power stations). For the Mediterranean region only it also contains information on land resources (soil erosion risk and land quality), coastal erosion, seismic risk and stream discharge.

7.3.3.2 Soils

Soils are the critical life-support surfaces on which all terrestrial biodiversity depends. There is an urgent need for

a global review of the distribution of soil types and changes in their status (e.g. desertification, salinization). Soil loss results in the loss of terrestrial biodiversity and can also severely affect aquatic biodiversity through the silting up of rivers, lakes, swamps and delta areas.

Soils contribute to biological diversity together with other environmental factors such as near-surface climatic conditions, landforms, surface and subsurface hydrology and the spatial and temporal variation in geomorphological processes. Soils are highly diverse in form and many different soil types can occur in a small area. The macro- and micro-fauna and the micro-biota in soil are an inherent part of the biological diversity of any area.

Modification of the biological diversity in soils under various forms of land use is an important area of enquiry. Mono-cropping of arable lands, with high inputs of mineral fertilizers and chemical control of diseases and pests, decreases the diversity of species both above and below ground, or at least makes them inactive (e.g. rhizobia, mycorrhiza). On the other hand, long-term mixed farming by smallholders who utilize the local variation of physiographic conditions can increase the diversity of cultivated and domesticated species. These so-called landraces are a valuable asset of traditional farming communities and the study of such diversity deserves more systematic attention.

Research on the relation between land use and biological diversity is at a very early stage. It is, however, important to realize that soils are providers, storers and generators of biodiversity.

7.3.3.3 Marine Station Networks

Logistically, it has been relatively easy to promote international co-operation in the inventorying and monitoring of marine biodiversity. This is essentially because many countries have, over the years, set up stations to study marine biology and have a common scientific tradition which predisposes them to co-operative programmes and networking (Lasserre *et al.* 1994; see Section 8.7). They are ideally placed in terms of their facilities, expertise, long data sets and geographical location to make a major contribution to inventorying and monitoring biodiversity (Grassle *et al.* 1991).

Although the coverage of the world coastline is incomplete, and the collecting effort and taxonomic extent of existing studies have been very uneven, many marine stations have published inventories describing the distribution patterns of marine species. A major challenge is to build up this co-ordination, taking account of the multiple habitat requirements, and the possible very wide distributions, of many marine organisms (planktonic larval life and many invertebrates and fishes), as well as the ocean-wide migrations of tuna, turtles, seabirds, seals and whales. Another challenge is that of studying the dynamics of marine biodiversity as the ecological processes concerned operate on very long time scales (Lasserre 1993; see Section 8.7).

On a regional scale, examples of networks include:

- **MARS:** Europe has a particularly long tradition in marine biology, and many marine stations have celebrated their centenary. In 1990, 11 European marine stations, established the Marine Research Stations (MARS) network, whose membership has subsequently been enlarged to approximately 80 stations. Collaborative biodiversity research is intended to include observational and experimental studies of ecosystems and extensive studies of diversity along Atlantic latitudinal gradients from Spitzbergen to the Canary Islands and along Mediterranean longitudinal gradients from Gibraltar to Haifa. This will facilitate the investigation of changes such as those recorded in seaweeds and the macrobenthos in the English Channel and related to temperature fluctuations of approximately 0.5 °C (Southwood 1980).
- **CARICOMP:** The Caribbean Coastal Marine Productivity (CARICOMP) programme is a regional network of 21 marine laboratories in 16 countries for the investigation of marine biodiversity. It began in 1985 with the support of UNESCO's Coastal-Marine Programme (COMAR), in response to a widely perceived need for regional understanding of the

long-term dynamics of coastal ecosystems upon which increasing human impact was superimposed. A methods manual was written in 1990 containing standardized protocols for monitoring the structure and function of the Caribbean's coastal ecosystems – as well as key physical time-series variables. In 1991, a Data Management Centre was established at the University of the West Indies in Kingston, Jamaica, and a basic set of monitoring equipment was distributed to all participants. Data collection according to the protocols began in 1993. Close communication will also enable the Centre to warn the network of regional phenomena such as coral bleaching, plankton blooms and major storms, that may require special observations.

7.3.3.4 Large Marine Ecosystems

Large Marine Ecosystems (LMEs) were defined in 7.2.10.4 as regions of ocean space encompassing coastal areas from river basins and estuaries on out to the seaward boundary of continental shelves and the seaward margins of coastal current systems. They are relatively large regions, in the order of 200 000 km² or larger, characterized by distinct bathymetry, hydrography, productivity, and trophically dependent populations (see Box 7.2-6). The theory, measurement and modelling relevant to monitoring the changing states of LMEs are discussed in reports on ecosystems with multiple steady states, pattern formation and spatial diffusion within ecosystems (e.g. AAAS 1986, 1989, 1990, 1991, 1993; Beddington 1986; Mangel 1991; Levin 1993).

The designation and management of LMEs is an evolving scientific and geopolitical process (Morgan 1988; Alexander 1989; AAAS 1993). However, sufficient progress has been made to permit useful comparisons to be made among various processes influencing large-scale changes in ecosystem status, health and biomass yields (Bax and Laevastu 1990; Bakun 1993). One recent finding is a marked decline in biodiversity among principal fish stocks of the Black Sea – believed to be partly due to the introduction of a 'foreign' species of ctenophore which causes severe predation on the early life-stages of both fish and their prey (Mee 1992). A second area of concern for scientists engaged in LME studies is the influence of changes in the gene pool of wild stocks from inadvertent releases of cultured stocks.

Among the LMEs being assessed, monitored and managed from a more holistic perspective are:

- the Yellow Sea Ecosystem: largely managed by the People's Republic of China (Tang 1989);
- the multi-species fisheries of the Benguela Current Ecosystem: South Africa (Crawford *et al.* 1989);

- the Great Barrier Reef Ecosystem and the Northwest Australian Continental Shelf Ecosystem: Australia (Bradbury and Mundy 1989; Kelleher 1993; Sainsbury 1988), and
- the Antarctic Marine Ecosystem under the Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR): 21 nations (Scully *et al.* 1986; Sherman and Ryan 1988).

Movement towards ecosystem-level assessment, monitoring and management is emerging also for the North Sea (North Sea Task Force 1991), the Barents Sea, the Black Sea (Hey and Mee 1993) and the Northern California Current Ecosystem (Bottom *et al.* 1989).

The broad-spectrum approach to LME research and monitoring provides a conceptual framework for collaboration in process-orientated studies conducted by the National Science Foundation-NOAA sponsored, GLOBal Ocean Ecosystems dynamics (GLOBEC) programme of the United States and the International GLOBEC programme (GLOBEC 1991). Developing LME monitoring strategies are compatible also with the proposed Global Ocean Observing System (see below), especially those modules focused on living marine resources and ecosystem health (IOC 1993).

Efforts are under way to place a greater emphasis on the linkage between scientific and societal needs and the utility of long-term, broad-scale coastal ocean assessment and monitoring aimed at improving the long-term sustainability of marine resource species. The basis for the linkage was emphasized in the UNCED declarations on the oceans and the ratification of the Biodiversity Convention. The scientific framework in support of these UNCED initiatives is now emerging from a series of regional efforts aimed at the integration of research, monitoring and assessments conducted to mitigate stresses on coastal ecosystems caused by toxic effluents, habitat degradation, nutrient loadings, harmful algal blooms, aerosol contaminants and losses of living resources from pollution and over-exploitation.

Biodiversity studies can contribute more towards the achievement of marine sustainability and the restoration of degraded biodiversity when they are conducted within a multidisciplinary scientific framework and focused on populations, habitats and ecosystems of large spatial scales. The driving forces of variability in biodiversity and biomass yields are currently being examined in several LMEs, along with observations on the changing states of 'health' of these systems (Sherman 1994). Marine resource problems underscored by UNCED, particularly as they affect human population requirements for nutritional well-being and national economies in coastal nations of Africa, South America and Southeast Asia, are being addressed. Post UNCED, LME-scale programmes for advancement

toward biodiversity sustainability, ecosystem health and economically viable biomass yields are being implemented for several LMEs adjacent to developing nations. The programmes are being supported by international agencies, as part of an effort to couple recent advances in ecological monitoring, management and stress mitigation strategies from the more developed countries with the less developed coastal countries around the margins of the ocean basins.

The GEF, in collaboration with NOAA, IOC, UNEP, FAO, the UK Natural Environment Research Council (NERC), the Sir Alister Hardy Foundation for Ocean Science and scientists from national marine resource agencies of several of the more developed countries (including Belgium, Canada, Denmark, France, Germany, the Netherlands, Norway and the United Kingdom) is assisting developing nations to implement coastal ecosystem assessment, monitoring and mitigation programmes, aimed at providing a scientific basis for improving the prospects for the long-term sustainable development of marine resources (Sherman *et al.* 1992). Two of these programmes are in the advanced planning stage: one for the Gulf of Guinea Ecosystem, brings together five countries of the region (see Box 7.3-5), while the second is being developed jointly by marine specialists from China and Korea for the Yellow Sea large marine ecosystem (Wu and Qui 1993).

7.3.4 Integration with programmes monitoring physical variables

7.3.4.1 Global Terrestrial Observing System (GTOS)

The Global Terrestrial Observing System (GTOS) is a joint initiative by the Food and Agriculture Organization (FAO), the World Meteorological Organization (WMO), the United Nations Environment Programme (UNEP), UNESCO and the International Council of Scientific Unions (ICSU), aimed at improving our understanding of the ways in which terrestrial systems respond to global change. By integrating and expanding existing monitoring sites and systems, GTOS aims to provide a co-ordinated, permanent, observational framework with adequate spatial coverage and temporal continuity to produce data to enable us:

- to detect and understand the impacts of national, regional and global change on terrestrial and freshwater ecosystems;
- to assess the responses of ecosystems to such changes and their role in causing them;
- to quantify and map all changes from local to global scales;
- to assess the consequences of changes for land use, biodiversity, biogeochemical cycles and climate change, and

- to develop, calibrate, validate and operate models from local to global scales (Norse 1994).

GTOS will also support the integrated assessment of changing socio-economic forces and ecosystem responses.

The mechanism proposed for GTOS is a four-level hierarchical observation system (Norse 1994). Level IV will be the least complex, but geographically most extensive, consisting of around 10 000 small (about 1 ha) sites which are to be established globally. These will monitor, at 5–10 year intervals, a few standardized, easily and cheaply measured variables (e.g. soil carbon) using both site visits and remote sensing. Level III will consist of approximately 1000 sites including existing national ecological and monitoring sites and agricultural research stations, selected to represent the major biomes, agro-ecological regions and farming systems. These will provide data on phenology, net primary production and other dynamic variables at sub-annual intervals. Level II sites will also represent major biomes, agro-ecological regions and farming systems. There will be approximately 100 sites, consisting mainly of existing major research centres, which will study a wider range of variables and monitor these more frequently (e.g. the continuous monitoring of fluxes of CO₂ in water). There will be 10–20 Level I sites, including a range of Level II, III and IV sites drawn from recent or ongoing international experiments. These will monitor changes in large-scale processes (e.g. soil transport and the movement of biota).

GTOS should meet both the practical needs of planners and policy-makers and the more comprehensive

requirements of the research community. It will provide a global framework for national ecosystem monitoring schemes, a method for relating local monitoring activities to global processes, and permanent ground truthing stations for the remote sensing of changes in vegetation distribution and related shifts in biological processes (Norse 1994).

Many of the sites and some regional and global ecosystem monitoring networks are already established. This, together with recent advances in data integration and communication systems, should enable GTOS to be 80% operational within five years (Norse 1994).

The Royal Geographical Society in London is developing a Geographical Observation Programme (GOP) to establish five or six permanent field stations to monitor global environmental change, and to provide a platform for local and regional environmental monitoring, research, training and education priorities. GOP will adopt global protocols where they exist and will integrate with GTOS.

7.3.4.2 *Global Ocean Observing System (GOOS)*

Set up by UNESCO's Intergovernmental Oceanographic Commission, the Global Ocean Observing System (GOOS) is a permanent international system for gathering, processing and analysing oceanographic observations from the open ocean and from coastal and shelf seas. GOOS products will describe and predict the state of the world ocean at regular intervals and will be available to all nations. The system will operate on three geographical scales. Globally, GOOS will provide the observations system and data delivery necessary to produce consistent data sets for ocean–atmosphere coupled with modelling and other global

Box 7.3-5: The Gulf of Guinea Large Marine Ecosystem (LME) Biodiversity Project.

The countries bordering the Gulf of Guinea are presently inhabited by 150 million people. By the year 2000, the number of people may increase to approximately 300 million. The nutritional needs of these people can be met in part from the marine resources produced within the Gulf of Guinea LME. The ecosystem is rich: approximately 1 million metric tons (1 mmt) of fish are caught annually. The economies of the coastal countries are being diversified to accelerate economic growth, employment opportunities and the raising of living standards. However, at present the near-coastal areas of the ecosystem are under growing environmental stress. It is essential to provide a more balanced approach to economic development and the sustainability of marine resources and coastal habitats. The evolving growth of petrochemical, fertilizer, paper products and metals industries has led to significant levels of coastal pollution. To provide a regional framework for mitigating stresses on the ecosystem, the Global Environment Facility, in collaboration with UNDP, UNIDO, UNEP, NOAA and FAO, is supporting a project to conserve marine biodiversity and control water pollution and sustain biomass yields of the Gulf of Guinea LME. The project, to be initiated in late 1995, consists of a core effort to conserve biodiversity by assessing, monitoring and mitigating the stresses on the LME.

The project components will include monitoring the biodiversity of fish and plankton, and ecosystem health. This information will be linked to an over-arching management protocol for linking stress mitigation to economic development. Participating countries include the Côte d'Ivoire, Ghana, Nigeria, Cameroon and Benin. Collaborating scientists, economists and natural resource managers from several of the more industrialized countries (e.g. USA, UK, Germany, Norway, Sweden, Denmark and France) will participate in expediting the transfer of technological advances in ecosystem monitoring and management practices.

products. The main benefits will accrue through the study, monitoring, understanding and prediction of global climate change and global climate monitoring. These global data will be interfaced with regional and national activities, including data gathering, modelling and special applications. The main benefits at these levels will be improved operational and design data for marine industries services and environmental management.

GOOS will gather data by remote sensing, sea-surface and sub-surface instrumentation. If the models used to explain future change are to show adequate precision, the long-term monitoring of the ocean will need to integrate physical, chemical and ecological data. To detect change, it is necessary to have long time series. Monitoring programmes, such as the Continuous Plankton Recorder, will be continued. However, surrogate measures of biological communities, such as acoustics, optical counting and image recognition, need to be developed and calibrated against classical sampling to make appropriate time/space scale measurements in real time. GOOS will provide data from its ecosystem health and living marine resource modules that will contribute to the assessment and monitoring of changes in the biodiversity of fish, shellfish and plankton species groups and ocean conditions.

The development of GOOS requires the testing and operating of many existing and new technological systems in a global suite conveying data on a strict timetable to super-computers which assimilate and analyse the data and then provide descriptions and forecasts of the state of the ocean and coastal seas. Global scientific programmes at present under way or planned include: the World Ocean Circulation Experiment, the Tropical Ocean Global Atmospheric Project and the Joint Global Ocean Fluxes Study. These provide the basis for the design of GOOS. Work is needed in equipment specification, testing and trials development of operational procedures, procurement of equipment and services, and progressive merging and testing parts of the whole system. Equipment, vessels, satellites and personnel will be dedicated to the GOOS by participating nations and will remain under national control.

7.3.4.3 Global Climate Observing System (GCOS)

The Global Climate Observing System (GCOS) was established jointly by the International Council of Scientific Unions, the World Meteorological Organization, UNESCO's Intergovernmental Oceanographic Commission and UNEP to develop an effective system to monitor the world's climate, detect climate change and predict climatic variation and change (Spence 1994). It is recognized that an integrated and comprehensive approach is necessary, incorporating all climate system components: the global atmosphere, the world oceans, the land surface, the cryosphere and the biosphere. The proposed Initial Operational System for GCOS includes:

- existing essential observational components for climate;
- necessary improvements which can be immediately identified and implemented, and
- a comprehensive data system.

All these elements should be operational over the next decade and five advisory panels (covering atmosphere, oceans, land/ecosystem, data and space-based observations) have been established to consider how best to implement the Initial Operating System (Spence 1994). The importance of integrating GCOS with existing research programmes (such as the World Climate Research Programme and the International Geosphere Biosphere Programme) and operational activities (such as World Weather Watch, the Global Atmosphere Watch and the Integrated Global Ocean Services System), as well as with developing programmes such as GTOS and GOOS (see 7.3.4.1 and 7.3.4.2), is also recognized.

Contributing to the establishment of GCOS, a baseline upper-air network of weather observing stations is being developed, alongside a reference surface network. Both of these will optimize the geographical coverage, reliability and quality of records (Spence 1994). GCOS is also co-operating with ocean programmes to increase the numbers and coverage of drifting buoys providing surface observations, and has helped to ensure the continuation of the Tropical Ocean Global Atmosphere Programme as a source of climate data for research and operational prediction.

Ultimately, GCOS will provide an international mechanism for the co-ordination of climate observations and will contribute to capacity-building and training projects for climatic research in participating countries (Spence 1994).

7.3.5 Inventorying and monitoring for conservation

A number of existing international agreements are concerned with inventorying and monitoring ecosystems and species for their safe use and conservation, some of which are discussed here.

7.3.5.1 The Ramsar Convention

The Ramsar Convention (1971) is an international treaty that provides a framework for the co-ordinated designation and conservation of internationally important wetland habitats. As of 1994, 81 states were Contracting Parties to the convention and 654 Ramsar wetlands had been designated, covering an area of over 43 million hectares (Navid 1994). This convention has generally been very successful.

7.3.5.2 CITES

The Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) (1973) provides an international legal framework that aims to control, reduce

or eliminate the international trade in threatened species whose numbers and conditions suggest that further removal of individuals would be detrimental to species' survival (Favre 1989). It includes Appendix I which lists those species that are in danger of extinction and banned from international commercial trade, and Appendix II that lists species which might become endangered and for which trade must be effectively regulated. One hundred and thirteen countries are now parties to the convention (WCMC 1992), all of which submit annual reports of their trade in listed species to the Convention Secretariat. From these reports, global levels of trade in species may be assessed and monitored in relation to the state of populations in the wild. CITES also provides information on trends in trade and in routes of trade over the short and long term. CITES has had mixed success, and issues such as the ivory trade have been hotly debated (see also Sections 13.3.5 and 13.6.4).

7.3.5.3 Species Survival Commission (IUCN)

Established in 1949, IUCN's Species Survival Commission (SSC), which now has approximately 3500 members in 135 countries (WCMC 1992), has been very successful. Its aim is to promote action to arrest the loss of the world's biological diversity and to restore threatened species to safe and productive population levels, and it provides an excellent forum through which amateurs and professionals can make a direct contribution. The SSC is divided into 95 Specialist Groups which cover different taxonomic groups, geographical areas or subject areas. The taxon-based Specialist Groups are responsible for reviewing the status and requirements of their taxon and for producing Action Plans for their effective long-term conservation.

7.3.5.4 World Conservation Monitoring Centre (WCMC)

The World Conservation Monitoring Centre (WCMC) was founded in 1988, jointly by the World Conservation Union (IUCN), the United Nations Environment Programme (UNEP) and the World Wide Fund for Nature (WWF), having previously been the IUCN Conservation Monitoring Centre. Its aim is to support conservation and sustainable development by providing technical services and authoritative information on global conservation issues. WCMC's global database includes information on national parks and protected areas, threatened plant and animal species and habitats of conservation concern. WCMC also undertakes research into the status, management and utilization of these resources. This information may then be provided to such groups as scientific institutions, conservation and development organizations, governments, commercial businesses and the media.

7.3.5.5 Red Data Books and Red Lists (IUCN)

The IUCN *Red Data Books*, produced by the SSC in collaboration with WCMC, are a range of authoritative

volumes providing information on the current status and conservation requirements of globally threatened species (see 7.2.8.3.2). For each taxon identified as threatened, the *Red Data Books* give an assessment of its distribution, population status, habitat and ecology and potential conservation measures. The volumes are divided on a taxonomic or geographical basis. To date, along with national volumes, *Red Data Book* publications include: *Dolphins, Porpoises and Whales of the World* (Klinowska 1991), the *ICBP/IUCN Threatened Birds of the Americas* (Collar *et al.* 1992), *Threatened Birds of Africa and Related Islands* (Collar and Stuart 1985), *Threatened Primates of Africa* (Lee *et al.* 1988), *IUCN Invertebrate Red Data Book* (Wells *et al.* 1983), the *IUCN Amphibia-Reptilia Red Data Book* (Groombridge 1982), the *IUCN Plant Red Data Book* (Lucas and Syngé 1978) and *Plant Red Data Book of Rodrigues* (Strahm 1989).

The *Red Lists* for threatened animals are published, generally on a two-year cycle, by WCMC in collaboration with IUCN-SSC and Birdlife International. These volumes provide a global inventory of species or subspecies that are known to be, or are suspected of being, extinct or threatened with extinction in the wild. The information is supplied by the SSC Specialist Groups, national *Red Data Books*, and scientists and naturalists working in the field. The 1994 *Red Data List* contains information on a total of nearly 6000 species (WCMC 1993). However, the species represented are not evenly distributed among taxa. Provisional assessments cover all birds, just over 50% of mammals (but many insectivores, rodents and microbats are not included), 20% of reptiles, 12% of amphibians and under 10% of fish. A small proportion of invertebrate species are also included, mainly dragonflies, butterflies and molluscs (WCMC 1993).

7.3.5.6 Stud Books and the International Species Inventory System

These systems have been designed for monitoring the genetic resources of vertebrates in captivity and facilitate the co-operation of different institutions in management plans for species. Stud books present an international register, listing all the captive individuals of a taxon, to help prevent inbreeding and improve the success of captive breeding programmes. Official stud books are recognized by the IUCN and the International Union of Directors of Zoological Gardens and are co-ordinated through the *International Zoo Yearbook* and the CBSG. In 1991 there were 104 recognized international stud books and five international registers. Since 1984 the stud book system has been supplemented by the International Species Inventory System (ISIS), a global network designed to help the management of zoological collections and to enable zoos to meet their increasing conservation responsibilities (see Section 8.6). ISIS maintains a centralized computer

database of census, demographic, genealogical and laboratory data for wild species held in captivity. The coverage for North America, Europe and Australasia is good but that of Asia, Africa and Latin America needs improvement (see Section 8.6).

7.3.6 Co-ordinating the inventorying and monitoring of genetic resources

Co-ordinated efforts to inventory and monitor genetic variation and resources have so far focused on taxa of economic or aesthetic value, mainly domestic or agricultural species and their wild relatives. Furthermore, until recently efforts were largely aimed at plant genetic resources with animal resources being largely ignored (WCMC 1992). Several groups play an important role in co-ordinating efforts at the genetic level and these are discussed below.

7.3.6.1 The Food and Agriculture Organization of the United Nations (FAO)

FAO has played a major role in research and conservation of forest genetic resources, stimulating many different programmes and initiatives. FAO's Global System for the Conservation and Utilization of Plant Genetic Resources was set up in 1983 to co-ordinate the conservation and use of genetic resources primarily for food and agricultural production (Glowka *et al.* 1994) and includes two major developments:

1. The International Undertaking on Plant Genetic Resources, which aims to ensure the unrestricted exploration, collection, conservation, evaluation and utilization of plant genetic resources, of present and future economic importance, for plant breeding and scientific purposes (Cossalter *et al.* 1993; Glowka *et al.* 1994).
2. The Commission on Plant Genetic Resources (CPGR), which is an international forum of over 125 countries, including representatives of donors and users of plant genetic resources, technology and funds which discusses matters related to plant genetic resources and monitors the implementation of the International Undertaking (Cossalter *et al.* 1993; Glowka *et al.* 1994).

Through the CPGR, international agreements have been, or are being, negotiated in three areas. First, to provide guidelines for the collection and transfer of plant genetic resources. Second, to promote the use of biotechnology for the conservation and sustainable use of plant genetic resources. Third, to place the collections and *ex situ* plant genetic resource bases of different states and institutions under FAO auspices to be held in trust for the global community (Glowka *et al.* 1994).

The Global System also includes the World Information and Early Warning System, a network of *ex situ* collections under the jurisdiction of the FAO and a developing network of *in situ* conservation areas (Glowka *et al.* 1994).

The FAO Panel of Experts on Forest Gene Resources is a statutory body which guides the FAO's activities in this area. It meets every three years and compiles and updates a list of tree species needing priority action in exploration, collection, evaluation, utilization and both *in situ* and *ex situ* conservation (Cossalter *et al.* 1993; Palmberg-Lerche 1994).

The Fourth International Technical Conference on plant genetic resources is scheduled to be organized by FAO in 1996 to examine information on the State of the World's Plant Genetic Resources and discuss an Action Programme on Plant Genetic Resources. Prior to this, a number of regional and sub-regional workshops will be held, covering both crop and forest genetic resources (Palmberg-Lerche 1994). Among the subjects discussed will be the results of a series of questionnaires on the status of crop plant and forest genetic resources sent to all Member States.

By 1994, contractual agreements have been made between FAO and national institutes in several countries to further the assessment, management, monitoring and conservation of the genetic resources of a number of species, including the heart-of-palm (*Bactris* spp.), medicinal forest plants, agroforestry species and rattans (Palmberg-Lerche 1994).

7.3.6.2 The Consultative Group on International Agricultural Research (CGIAR)

Founded in 1971 jointly by the World Bank, FAO and UNDP, CGIAR is a consortium of donor countries, foundations and development banks which supports a network of 16 International Agricultural Research Centres (IARCs) and 227 seed banks in 99 countries (see Section 8.8.4). Most of the IARCs are concerned with the development of crop varieties and conservation of germplasm collections, some of which provide international bases for specific crops.

Both CGIAR and the IARC network have been active in the international co-ordination of activities concerning plant genetic resources (WCMC 1992). Perhaps the most important IARC in this respect is the International Plant Genetic Resources Institute (IPGRI). Originally established in Rome in 1974 as the International Board for Plant Genetic Resources and renamed in 1992, IPGRI has had a co-ordinating role in setting priorities and creating a network of national programmes and regional centres for the conservation of plant germplasm. With the assistance of IPGRI, 90% or more of the known landraces of crops such as wheat, corn, oats and potatoes and an estimated 510 000 accessions, are held by the IARCs and seed banks. IPGRI also has links with over 500 institutes in 106 countries (WCMC 1992).

On a national and regional level, many institutions play an important role in the collection, conservation and investigation of plant genetic resources. These include the Sub-Saharan National Tree Seed Centres of Burkina Faso, Kenya, Rwanda and Zimbabwe; The Plant Genetic Resources Centre in Ethiopia; the ASEAN-Canada Forest Tree Seed Centre in Thailand; CATIE in Costa Rica; Brazil's national research organization for agriculture and forestry, and National Genetic Resources Centre, and the International Centre for Agricultural Research in the Dry Areas in Syria (Cossalter *et al.* 1993). Furthermore, several regional forest genetic resources networks and programmes are now operating, covering areas of Africa, Southeast Asia and Central America and providing international co-ordination and support (Cossalter *et al.* 1993).

7.3.7 Sites for inventorying and monitoring biodiversity

Throughout the world there are many areas that have some degree of protection or other, and many have been designated as national parks or reserves. In addition, other sites have been established for ecological or environmental research. Although many of these are in areas that are of some importance with respect to their biodiversity, or are environmentally sensitive, others have less significance and have been established, at least in part, for non-biological reasons. With limited resources for conservation of biodiversity and increasing demand for lands for development, governments are faced with having to establish priorities for the conservation of land. A number of methods have been developed to help in this prioritization: all are dependent on systematic information from biological inventories (see 7.1.4).

A number of the initiatives discussed above utilize specific sites for inventorying and monitoring and it is clear that there needs to be some sharing of resources and integration of programmes. Probably the most important global system of sites is the Man and the Biosphere network organized by UNESCO. The programme appears to be well positioned to make significant contributions as a resource base for biodiversity assessment, both nationally and internationally, in connection with the marine station networks. Indeed, there exists a significant potential to build a functional international network for biodiversity research related to management from the coastal Biosphere Reserves. MAB intends to contribute to the collaborative efforts designated to detect the responses of marine and coastal ecosystems to global change; to contribute to collaborative research projects on sustainable development at the land-sea boundary; and, in general, to link biosphere reserves to other international marine networks. EuroMAB is undertaking a joint project to create a Biosphere Reserve Integrated Monitoring Network (BRIM) in conjunction with US MAB. Other recently created Biosphere Reserve networks include the Ibero-American Programme (MAB-

CYTED) devoted to biodiversity, the China Biosphere Reserves Network (CBRN-MAB), the Northern Science Network promoting co-ordinated research in Biosphere Reserves, and the MAB-GEF network on Biodiversity conservation in Biosphere Reserves of Central Europe. The activities concentrate on (1) inventorying and monitoring biodiversity, (2) conserving and sustainably using biodiversity, and (3) communication and policy information for decision-makers (Box 7.3-6). However, even with this programme there are large gaps in coverage. For example, there are few biosphere reserves in South America and Africa in the 'hot-spots' or megadiversity countries. If this network is to be used as a base for co-ordinated inventorying and monitoring then it will need to be considerably expanded to include sites in areas such as the southern Guianas, the upper Amazon lowlands, the Zaire Basin and New Guinea.

As has already been stressed in Chapter 7.2, long-term study sites, such as the LTER system in the USA, are essential if monitoring changes are to be effective.

7.3.8 Global co-ordination: GIMP

It is clear from the preceding parts of this chapter that many aspects of inventorying and monitoring are poorly addressed as a result of lack of resources, direction or co-ordination. This problem may be overcome either by expanding the role of existing organizations or by the establishment of an international programme with the specific role of co-ordinating and increasing the effectiveness of inventorying and monitoring efforts. In Box 7.3-7 an outline is suggested for the remit of a Global Inventorying and Monitoring Programme that might address the issues involved. Such a programme should include a periodic global assessment that:

- is all-encompassing, i.e. includes integrated and continuous estimates of grasslands, forests, agricultural lands, wetlands, etc;
- provides biodiversity estimates as they apply to food, fuel, shelter, employment and the environment;
- includes environmental and social considerations in addition to economic factors as noted above;
- reflects the latest technology, data acquisition and sharing, and display, and presents facts so that people can understand and authorities can make rational policy decisions: this would include maps showing: (1) distribution of the Earth's resources, (2) current Earth cover, (3) where pressures exist and predictions of where they will occur in the future, and (4) where opportunities exist for meeting human needs (Lund 1993).

Such a structure might facilitate the links needed between programmes such as GTOS, GCOS, GOOS, DIVERSITAS and Systematics Agenda 2000.

In developing the GIMP, it is our vision that:

1. Each participating country will have the capacity and tools to inventory its resources, provide information for decisions, and monitor the impacts of land and resource management.

Box 7.3-6: UNESCO's Man and the Biosphere Programme and the Biosphere Reserve Network.

UNESCO's Man and the Biosphere (MAB) Programme was launched in 1971 to improve the links between people and the biosphere. Some 110 countries co-ordinate their national contributions under MAB National Committees. MAB's priority themes for 1996–2001 are:

- conserving biodiversity and ecological processes;
- exploring approaches to land-use planning and sustainable management of natural resources in regional landscapes;
- formulating and communicating information on sustainable resource management and promoting corresponding environmentally sound behaviour, and
- building up human and institutional capacities for land-use planning and sustainable resource management.

The idea of co-ordinating studies of natural systems at national, regional and international levels was inherent in the setting up of the International Biosphere Reserve Network, the backbone of the MAB programme. Biosphere Reserves are alternative types of protected areas with a combination of functions including *in situ* conservation of natural and semi-natural areas, sustainable management of natural resources for local people, scientific research and monitoring, and environmental education and training. As of June 1995 there are 324 biosphere reserves located in 82 countries.

The strategic plan for Biosphere Reserves refers specifically to actions for the inventorying and monitoring of flora and fauna. One effort to promote such work has been the preparation of a directory of contacts and environmental databases for Biosphere Reserves in Europe and North America (EuroMAB 1993). Of the 175 Biosphere Reserves in this directory, over 88% had undertaken a biological inventory and possessed collections of local fauna and flora; 86% also monitored climatic parameters, 76% monitored various data on vegetation and 76% monitored wildlife population dynamics. These high figures fall considerably for Biosphere Reserves in some other parts of the world, where the reserves range from long-established sites with good inventories of flora and fauna and monitoring programmes, to new sites which have not had the time to develop such activities, to those that do not possess the capacity to collect such data.

At the regional level, a number of sub-networks of Biosphere Reserves exist, and these undertake inventorying and monitoring of biodiversity as part of their activities.

- The *Observatoire du Sahara et du Sahel* monitors desertification in 20 countries of the Sahara and Sahel region of Africa, emphasizing the human uses of biological resources (OSS, 1994).
- The Ibero-American Network of Biosphere Reserves organized under CYTED (*Programa Ibero-americano de Ciencia y Tecnología para el Desarrollo*) involves 19 countries of Latin America and the Caribbean plus Portugal and Spain and specifically addresses the inventorying and monitoring of biodiversity in the Biosphere Reserves of these countries (Halfpter 1992).
- The Biosphere Reserves Integrated Monitoring system set up for 175 Biosphere Reserves in 32 countries in Europe and North America (EuroMAB) is a compilation of existing inventorying and monitoring activities in these sites that facilitates collaboration among participating scientists (EuroMAB 1993).

As a complement to the terrestrial element of the Biosphere Reserve Network and the growing number of Biosphere Reserves that encompass both terrestrial and marine parts, UNESCO also operates a COstal and MARine programme (COMAR) for scientific research and training in coastal and marine systems (see 7.3.3.3).

Box 7.3-7: Global Inventorying and Monitoring Programme (GIMP).

Priorities for a Global Inventorying and Monitoring Programme would be:

1. To establish and co-ordinate targets and timetables for systematics including making priorities for taxa, revisions, field guides and collection databasing.
2. To establish and co-ordinate rigorous standards for sampling and analysis of all groups of organisms for both inventorying and monitoring.
3. To establish and co-ordinate a network of areas for inventorying and monitoring at different levels of intensity, linking these with existing site networks (e.g. GTOS, GCOS, GOOS) to maximize the utility of data.
4. To establish and co-ordinate priorities for training at all levels (e.g. curator, information technologist, researcher, technician, parataxonomist, paraecologist, volunteer).

2. The international community will have current data for global assessments and research.
3. The information at the country level and international levels will be compatible.
4. National agencies and international groups will play a major role in achieving this vision by sharing the use of talents and resources through a co-ordinated programme that provides needed data, fills gaps and eliminates duplication.

7.3.9 Summary

Informed decisions concerning the mitigation of losses of global biodiversity can best be made when based on sound, scientifically based options. Many of the scientific data on biodiversity are difficult to synthesize because of their fragmentary character, limited comparability and inaccessibility.

Carefully planned standardization and calibrated temporal and spatial inventorying and monitoring efforts are required by the global community of nations in shared international efforts focused on regional efforts to mitigate the loss of global biodiversity.

If inventorying and monitoring of the biodiversity of regions or nations is to be increased to the levels demanded by international agreements such as the Biodiversity Convention and Agenda 21 or by scientific programmes such as DIVERSITAS (IUBS/UNESCO) or Systematics Agenda 2000, then this will require a vast increase in systematic and ecological infrastructure and human resources. Such capacity and infrastructure exceeds the capabilities of even the most advanced nations. In addition, biodiversity is not restricted by political boundaries and there is therefore a need to share expertise and resources.

Few countries have clear programmes to make inventories of their fauna and flora and the tools to identify

organisms. If museums, herbaria and other institutions charged with the task of providing the systematics services for inventorying are to carry out these tasks then they need to be much better resourced, their collections better maintained, and a new cadre of professional researchers and technicians trained and funded. The same is also true for the monitoring of biodiversity. Indeed, in many countries monitoring of biodiversity is almost non-existent.

7.4 Capacity building

7.4.1 Introduction

It is clear from this and other Sections of the GBA that if scientists are to attain a better understanding of the distribution and magnitude of biodiversity and are to provide better information on changes in biodiversity for management and sustainable use, then considerable

development of capacity for inventorying and monitoring will be required (see Box 7.4-1). Such problems are addressed in Articles 15.7–15.11 of *Agenda 21*:

- Article 15.7 promotes technical and scientific cooperation in the field of conservation of biological diversity and the sustainable use of biological and genetic resources. It notes that special attention should be given to the development of and strengthening of national capabilities, by means of human resource development and institution-building, including the transfer of technology and/or the development of research and management facilities, such as herbaria, museums, gene banks and laboratories related to the conservation of biodiversity.
- Article 15.7 also promotes national efforts with respect to surveys, data collection, sampling and evaluation, and the maintenance of gene banks.
- Article 15.9 addresses the scientific and technological means of implementation (quoted earlier).
- Article 15.10 addresses human resource development: (a) increase the number and/or make more efficient use of trained personnel in scientific and technological fields and (b) maintain or establish programmes for scientific and technical education and training of managers and professionals, especially in developing countries.
- Article 15.11 addresses capacity building with respect to strengthening existing institutions and/or establishing new ones responsible for the conservation of biological diversity and considers the development of mechanisms such as national biodiversity institutes or centres.

(summarized from Johnson 1993)

Capacity building for the inventorying and monitoring of biodiversity involves four areas in particular: physical infrastructure, human resources, communication, and availability of information. This chapter of the GBA provides an overview of the problems associated with the first two. The third and fourth areas are discussed in Section 9.

7.4.2 Development of institutional capacity

In Section 7.2 the importance of storing and maintaining collections of specimens for all organisms in museums, herbaria and other natural history institutions was stressed as such collections provide the firm base for most

inventorying and monitoring efforts. Section 8 notes that although in many countries there are well established institutions and organizations concerned with the inventorying and monitoring of biodiversity, such as museums, herbaria and botanic gardens, many of these are old, poorly equipped and poorly staffed. For these countries and those without such facilities the development and enhancement of institutional capacity for inventorying and monitoring is essential.

In addition to the strengthening of the infrastructure in such traditional areas as natural history institutions, other kinds of facilities are becoming increasingly more important. In particular, laboratories need to be adequately equipped for genetic surveys and for monitoring of biodiversity.

Many countries are faced with the need to develop their capacity to carry out genetic surveys. Establishing a laboratory for such and staffing it with trained personnel need not be excessively expensive relative to other scientific endeavours and relative to the possible scientific benefits. Older laboratory spaces can often be converted to accommodate molecular research. The initial costs of laboratory facilities will depend largely on the range of molecular techniques that will be required, and once the laboratory is established, the major costs will be for personnel and consumable supplies (Hillis and Moritz 1990; Zimmer *et al.* 1993; Suh *et al.* 1993; Avise 1994).

The growth of genetic surveys for enquiry into and management of biodiversity will necessitate a parallel growth in collections specifically designed to preserve tissues and their macromolecules. The facilities of many traditional natural history collections are being expanded to meet this need. This is critical because the scientific value of these genetic resources is enhanced when preserved with traditional voucher specimens. Like more traditional biological collections, tissue facilities also require constant curatorial attention.

Most countries have some infrastructures in place for conducting inventories and for establishing monitoring programmes, such as national forest survey units. These can be strengthened to help collect biodiversity information (Lund *et al.* in press). It is essential that funding be provided to strengthen these institutions.

The diversity of the biota in countries with tropical forests adds complexity to the practice of inventorying, but the problems encountered are generally financial rather than technical. Tropical foresters, for example, know how to design and implement an effective inventorying and monitoring programme (see, for example, Box 7.1-8, Malaysian Forest Inventory), but infrastructure limitations can make inventories excessively expensive relative to the budgets available for information gathering (Gillespie 1992). Unstable governments further jeopardize the success of long-term monitoring programmes.

Box 7.4-1: Capacity-building for inventorying and monitoring.

Increased inventorying and monitoring is needed for:

- collecting and housing specimens of plants, fungi, animals and microorganisms in natural history institutions;
- maintaining germplasm of crops and breeding populations of animals;
- understanding the status of pests of agricultural, medical and veterinary importance;
- understanding the threatened status of rare and threatened organisms;
- mapping the distribution of organisms and monitoring changes in their distribution;
- monitoring the state of protected and non-protected areas;
- monitoring changes in the patterns and intensity of land use, and
- monitoring levels of pollution.

Other problems with large area or ecosystem inventories include lack of funds, lack of access to some parts of the world and lack of equipment. Critical factors in carrying out such biodiversity inventories include access, availability of information on existing data (e.g. maps, air photograph, past reports), access to technology and equipment (and especially replacement and repair) and training. Lund (1995) provides additional practical guidance in working with people to maximize data collection opportunities and to strengthen infrastructure capacity building.

7.4.3 Human resources and training

7.4.3.1 Local people and volunteers

Although there is clearly a lack of human resources in several aspects of inventorying and monitoring, there are opportunities for lateral thinking. The development of formerly untrained local people as 'parataxonomists' dedicated to the conservation and use of biodiversity in Costa Rica is one very good example. Such empowerment of local people is critical to the management of biodiversity and is often the cheapest and most effective method of achieving the goals of inventorying and monitoring. It is widely argued that the conservation of nature in general is best achieved through the involvement of local people (Janzen *et al.* 1993).

Non-governmental organizations and volunteers sometimes can play a critical role. In Britain for example, the British Trust for Ornithology (BTO) carries out an annual bird census throughout Britain, manned entirely by amateur bird enthusiasts. BTO's monitoring of bird populations over recent years has played an important part in detecting changes in biodiversity in Britain (Anonymous 1994).

Similarly, many inventorying and monitoring projects are supported in the field and laboratory through the

assistance of volunteers provided by organizations such as Earthwatch and youth development organizations such as Raleigh International. With the expansion of ecotourism throughout the developing world, the possible assistance of tourists and other volunteers to help in inventorying and monitoring needs further investigation.

The involvement of non-professionals or local people is enhanced by the development and implementation of simple techniques and simple tools: here butterfly nets and field guides are of more relevance than complicated extraction methods and detailed systematic revisions.

7.4.3.2 Development of a professional scientist cadre

The use of local people and volunteers for inventorying and monitoring should, however, supplement rather than substitute for trained graduate and postgraduate biologists with skills in systematics, ecology and related sciences.

The ability to identify organisms is essential to almost all aspects of biology. Many important organizations have noted the dramatic decline in numbers of systematists and the huge shortfall in skilled professional scientists if inventorying and monitoring is to be carried out at a satisfactory level in the future (Anon. 1991; Coddington *et al.* 1991; National Science Board 1989; di Castri *et al.* 1992a, b; SA2000 1994). The situation has become increasingly acute, first in universities and subsequently in many other developed country institutions, and is now a world-wide problem. Numerous organizations and task forces, such as the National Science Board Task Force on Global Biodiversity of the US National Science Foundation (1989) and the UK House of Lords Select Committee on Science and Technology (Anon. 1991) have concluded that effective management of the problem of declining global

biological diversity is severely hampered by the shortage of systematic biologists to identify, document and classify organisms (SA2000 1994).

In the UK, the number of scientists undertaking taxonomic or biosystematic research dropped from 552 in 1980 to 514 in 1990 (Anonymous 1991). The age spectrum of those still in post was also a matter for concern. In 1990, 63% were over 46 years old and only 8% under 35 years. The number of biosystematists in universities has halved each decade (Claridge and Ingrouille 1992). Gaston and May (1992) point out that if the same demographic trends were found in a newly discovered lemur, specimens would be brought into a zoo and a captive breeding programme initiated. The decline in the numbers of biological systematists in universities results in a consequent scarcity of relevant undergraduate and postgraduate programmes.

Systematics Agenda 2000 (1994) makes proposals for addressing this situation, for example by funding graduate students to work with the older existing specialists before they retire to ensure that their skills and knowledge are not lost.

Training merits special attention, and the use of biological systematists employed in museums and other institutions as specialist lecturers and supervisors of graduate students is to be encouraged. Short courses can be of immense value in imparting particular skills, and in training parataxonomists. The training of the professionals necessary to provide the skills base for biodiversity assessments world-wide is long-term. Following the completion of a PhD programme, in most groups of organisms, an aspiring specialist needs time to become thoroughly familiar with a wider complex literature, and experience a greater range of material: this is a lengthy process. Janzen (1993) estimated the cost of producing a trained taxonomist at US\$500 000 over ten years. Replenishing the human resource requires consideration in the development of national biodiversity action plans if they are ever to be effectively implemented.

To remedy the problem of the lack of skilled professionals in systematic biology in developing countries, it is imperative that local natural history institutions be strengthened and that linkages with institutions in the developed nations be established. Several developed countries have established programmes to assist the training of systematists, for example, the US has established Partnerships for Enhancing Expertise in Taxonomy (PEET) (Box 7.4-2).

Similarly, there is a shortage of skilled professionals for monitoring biodiversity. It is therefore important to build on existing structures to increase human resources in this field. The FAO Forest Resource Assessment for example, which has been built on the existing forest inventory programmes in many countries, and ongoing fisheries surveys conducted from research vessels of most coastal

nations, could be used to carry out broader biodiversity inventories of terrestrial and marine organisms.

In the UK the 'Darwin Initiative' has been established to help in training scientists in developing countries in many areas of biodiversity including inventorying and monitoring.

7.4.4 Conclusions

To maximize the resources and talents available for large area inventorying and monitoring in developing and emerging nations, those nations should consider:

- adopting a centralized or semi-centralized approach in the short term, to be matched by the international development community so as to establish an operational monitoring capability for remote sensing land cover within the national resource management agencies;
- involving national resource management agencies in the monitoring programme both as regards classification and validations and accuracy assessment;
- providing unrestricted access to the results of biodiversity surveys and supplying the output in a variety of media.

Donor organizations should:

- set an example by following international standards and guides, and by harmonizing data and making it available to the international community;
- work to establish inventory, assessment and monitoring activities that are compatible with each other;
- promote country capacity building, by helping nations develop to inventory and monitoring capabilities that will meet not only national needs but also international needs: this will be achieved through sharing of equipment, data acquisition, methodology training and on-site technical assistance on data base management, and through technology transfer;
- provide technical help in species identification and classification, image processing, analysis, vegetation mapping and use of geographic information systems, and
- provide guidance and expertise in field sampling efforts for vegetation resource inventory and monitoring.

7.4.5 Summary

- If inventorying and monitoring of the biodiversity of regions or nations is to be increased to the levels

Box 7.4-2: Human and informational capacity development: Partnerships for Enhancing Expertise in Taxonomy (PEET).

Recognizing the need to develop expertise for identifying and inventorying the Earth's biota, the US National Science Foundation has launched a new programme, Partnerships for Enhancing Expertise in Taxonomy (PEET). PEET aims to develop scientists who are experts in those taxonomic groups – such as microorganisms, fungi and most invertebrates – that are relatively under-studied but are critical elements of food chains and ecosystems. The high proportion of unrecognized, undescribed species in these groups limits research and progress in many areas of the biological sciences. PEET also supports the production of electronic databases about these under-studied groups, in order to produce knowledge bases with broad accessibility to the scientific community.

Each five-year PEET project includes three components:

- Taxonomic research on organisms that are little studied or for which taxonomic expertise is limited or vanishing, such as fungi, nematodes, molluscs, insects, bacteria and protists.
- Training of at least two student taxonomists (at the undergraduate, graduate, and/or postdoctoral levels) as experts on the organisms under study: emphasis is placed on including experts-in-training from biodiversity-rich developing countries.
- Preparation of computerized resources, such as specimen databases, artificial intelligence systems, computer-aided image analysis, and interactive keys.

PEET will help to reverse the loss of systematic expertise – caused by such factors as the retirement of taxonomic specialists, shifts in academic recruitment and staffing, and reduction in graduate training programmes in systematics – that is needed to characterize biodiversity and aid in its rational use.

demanding by international agreements such as the Convention on Biological Diversity and *Agenda 21* or by scientific programmes such as DIVERSITAS (IUBS/UNESCO) or Systematics Agenda 2000, then this will require a major increase in systematic and ecological infrastructure and human resources. Such capacity and infrastructure at present exceeds the capabilities of even the most advanced nations. In addition, biodiversity is not restricted by political boundaries and expertise and resources need to be shared.

- Few countries have clear programmes to make inventories of their own biota, or the tools to identify the organisms involved. If natural history institutions charged with the task of providing the taxonomic services for inventorying are to carry out these tasks then they need to be much better resourced, their collections better maintained, and a new cadre of professional researchers and technicians trained and funded.
- Similarly, few countries have adequate programmes to monitor biodiversity, whether in protected or non-protected areas. Additional resources are required to develop human and physical capacity for such monitoring.

EXECUTIVE SUMMARY

A wide variety of protected areas, scientific collections, living collections, genetic resource collections, information and human resources is necessary for biodiversity assessments at all levels. In general, these resources are in need of significant enhancement if nations are to be able to meet the obligations of the Convention on Biological Diversity.

- The number of protected sites is substantial, with no fewer than 8715 located in the tropics.
- Fewer than 5% of protected sites have been thoroughly inventoried for even one major group of the biota, and this restricts their value for the understanding and conservation of biodiversity.
- Biosystematic reference collections are the material basis for biodiversity assessments: they include anchors for the application of scientific names ('type collections') and a wealth of information relevant to inventory production and distributional studies.
- While there are some 2.5 billion specimens in such collections world-wide, most are in Europe and North America. They are generally undersourced and the data in them are difficult to access.
- The major documentation of biodiversity is located in developed countries: the number of pertinent periodicals alone is almost 13 000, and few libraries hold more than a fraction of these.
- Electronic services and delivery systems (on-line and CD-ROM) can facilitate access and document supply for post-1970 works, but vital earlier literature is not available in such formats.
- An estimated 1600 botanic gardens together hold over 4 million accessions which represent about 80 000 species of plants, i.e. about 30% of the known species and 25% of the estimated species on Earth.
- Extensive collections of cultivars exist, also mainly in developed countries.
- There are more than 2000 zoos, insectaries and aquaria world-wide, roughly two-thirds of which are in developed countries: 500 of these collectively hold 5900 species.
- Marine stations are widely distributed, and include a considerable number in the tropics. These are linked by a number of active regional networks.
- Genetic resource collections – repositories of living organisms, generally in a dormant or other phase where they are not actively growing – consist predominantly of species currently used by humans.
- Plant germplasm collections amount to some 4.32 million accessions. They represent some 6000 species, but about 3 million of the accessions relate to only about 100 species.
- In microbial groups, genetic resource collections are often the only practical source of species for research and evaluation purposes, and some permanently preserved cultures maintained in such collections can also be the 'types' of scientific names.
- The 482 collections of living cultures of fungi and other microorganisms collectively hold 786 328 strains representing the 3100 valid bacterial species, about 17% of the known fungi, and relatively smaller proportions of algae, protozoa and viruses.
- Molecular data are increasingly used in the objective assessment of biodiversity, and the sequence data generated are made available by particular centres for world-wide consultation on the Internet.
- Molecular libraries have a particular value for the retention of sequences of uncultured or unculturable bacteria and other microorganisms for which the sequence 'fingerprint' is often all that is known.
- The human resource required for biodiversity assessments includes biosystematists, 'amateurs', parataxonomists and indigenous peoples.

- While there may be 20 000–30 000 biosystematists world-wide, the number involved in the description of newly discovered species is about 7000, mostly based in Europe and North America, and has an age profile indicative of a declining population.
 - There is a major mismatch between the number of described species in different groups and that of the specialists working on them. The mismatch is even more striking when estimated rather than described species are considered.
 - The rate of description of new species has remained almost constant for the last 25 years. At the current rates of description it would take 575 years (i.e. until 2570) to describe the remaining unnamed 11.9 million species on Earth – *provided* that much of the workforce was redeployed to work on the most species-rich groups.
 - Progress on major floristic and faunistic projects, and biosystematic revisions, is slowed by current working practices and limited access to data. Lists of accepted species names in all groups, compilations of data in reference collections, improved bibliographic services, and simplified nomenclatural procedures would facilitate this work.
-

8.0 Introduction

This Section assesses the variety of resources and infrastructure available for biodiversity assessments including conservation, with a particular emphasis on those concerned with inventorying and monitoring and with the examination of the magnitude and distribution of biodiversity. In addition to discussing the nature and range of the resources available, the Section also considers their extent and adequacy for the tasks now to be addressed. Further details in Sections 2, 7 and 13 complement this assessment and are cross-referenced as appropriate in the text.

8.1 Historical considerations

The human, institutional and collection resources required for the assessment of the magnitude and distribution of biodiversity at its various levels are extremely diverse. Many of the key resources have, however, come to be concentrated in Europe and North America as a result of the history of exploration of Earth's biodiversity, although increasing numbers of countries in other regions have made significant progress in developing their own collection resources, for example Australia, Brazil, Costa Rica, India, Indonesia, Japan, Kenya, People's Republic of China, South Africa and Zimbabwe.

The tradition of collecting and documenting life on Earth has a long history from Egyptian times onwards. Accounts of medicinal and food plants appear in Aztec and Mayan codices and Chinese herbals; printed accounts with descriptions started to appear in the late fifteenth century; and in the first quarter of the sixteenth century, numerous herbals were produced in Europe. Initially these focused on plants of pharmacological value, but extended in the mid-sixteenth century to more general surveys, and by the end of the century a wide range of imaginatively illustrated treatments based on species in particular regions or systematic groups was available in Europe (Arber 1953; Burdet 1985).

The pace of collection and documentation accelerated through the periods of great exploratory voyages in the seventeenth and eighteenth centuries, and reached its zenith in the late nineteenth century. Sea captains were often also charged with collecting material and it became the norm for major seafaring expeditions to include a naturalist amongst their number: for example Sir Joseph Banks on Cook's *Endeavour* voyage which included much of the South Pacific in the years 1768–71, and Charles Darwin on HMS *Beagle* in 1831–36 (Tourtellot 1987). There were also spectacular overland expeditions, for example the exploration of the area between the Mississippi and the Pacific coast of North America by M. Lewis and W. Clark in 1804–6 and the celebrated voyages of Alexander von Humboldt in tropical America in 1799–1804.

Collections were generally brought back to the then European colonial powers, where major museums, collections of dried plants ('herbaria') and botanic gardens were founded and grew dramatically. Publications based on the collections were also produced almost exclusively in those countries.

This pattern has meant that the key reference collections and publications relating to the earliest periods of naming of the biota of the world are concentrated in Europe. Substantial collections have been developed subsequently in Australia, India, South Africa and especially the USA, and while these contain an immense amount of material relevant to biodiversity assessments (see 8.3.4 and Tables 8.3-1, 8.3-2), these do not include material from the first explorations – including the name-bearing 'type' specimens that anchor the application of the names of species. While this presents difficulties for countries in retrieving information directly related to the assessment of their biodiversity, it also has to be remembered that institutions able to store collections and publish on them did not exist in much of the world in the first period of expansive exploration. However, there are important institutions in other regions which do have major natural history collections, such as those in Bogor, Calcutta, Guangzhou and Nairobi, but it should be noted that maintaining collections, and paper materials, in tropical situations requires particular care as under warm and humid conditions they are more vulnerable to damage by termites and other insects and by mould fungi (Fosberg and Sachet 1965).

Species distributions do not conform to national boundaries, and as name-bearing types are the standards for the communication and application of scientific names, ease of access is an important consideration. Examining the locations of the name-bearing type specimens of newly published species gives a good idea of current practices in assembling reference collections. To locate such specimens it is usually necessary to look at the original publications of the names. However, in the case of the fungi, the *Index of Fungi* has since 1991 indicated the institutions where the primary name-bearing type material of newly described fungi has been deposited. Of 5573 newly described fungi, the name-bearing types of 2273 (41%) were deposited in collections other than those in the country of origin of the material (Hawksworth and Kirk 1995). For other groups, standard indices of names (Box 8.1-1) do not include such data so it is unclear to what extent this is a general problem. Where material is deposited in the country of origin, duplicates are also regularly deposited in the major world reference collections and a good argument can be made for continuing this practice in order to facilitate authoritative identifications and biosystematic research (Holloway 1983).

Box 8.1-1: Principal catalogues and indices of names of living species (all groups of organisms, excluding works dealing with fossils only).

‘Algae’ [incl. cyanobacteria]
Dawson (1962), De Toni (1889–1924), Drouet and Daily (1956), Vanlangingham (1967).

Bacteria [excl. cyanobacteria]
International Journal of Systematic Bacteriology (1980) on, Skerman, McGowan and Sneath (1989).

Bryophytes [anthocerotes, mosses, liverworts, etc.]
Bonner (1962 on), van der Wijk, Margadant and Florschütz (1959–69).

Flowering plants and ferns
Christensen (1906–65), Jarrett (1985), Index Kewensis (1895 on), Kew Index (1986 on).

Fungi [incl. lichen-forming fungi, slime moulds, and yeasts]
Deighton (1969), Hawksworth (1972), Index of Fungi (1940 on), Kirk (1985), Lamb (1963), Petrak (1930–44, 1950), Saccardo (1882–1931, 1972), Zahlbruckner (1921–40).

Viruses
Virus Identification Data Exchange (VIDE).

Animals [all groups covered by the International Code of Zoological Nomenclature] Neave (1939–93), Sherborn (1902–33), Zoological Record (1865 on).

8.2 Protected area systems

As countries plan their implementation of the Convention on Biological Diversity, the importance and relevance of protected area systems that encompass representative habitat types, conserve key biological resources, and allow for sustainable development initiatives has been reinforced. Protected areas, mainly established over the last 50 years, have varying degrees of legal protection and infrastructural support in terms of staff, equipment and budget, and collectively represent an important mechanism by which national investments in biodiversity can be assessed and monitored (McNeely 1993, 1994).

A major review of protected area systems has been prepared by McNeely *et al.* (1994), while more recent

statistics are provided by IUCN (1994a). This latter report, jointly prepared with the World Conservation Monitoring Centre (WCMC), shows that there are currently 9832 protected areas, covering more than 9.25 million km² – about 8.2% of the land on Earth. Protected sites are found in most of the biogeographical provinces defined by Udvardy (see Sections 2.3 and 13.4.2), and in all the major biome types, although their distribution is far from even politically or biologically. For a summary of the status of protected area systems, refer to IUCN (1992, 1994a), McNeely (1994), McNeely *et al.* (1994) and see Section 13.4.2.

Protected areas are classified by IUCN (1994b) under six broad management categories (see Box 8.2-1; Box 13.4-1).

Box 8.2-1: 1994 IUCN protected areas management categories.

Category I	Strict Nature Reserve / Wilderness Area: protected area ¹ managed mainly for science or wilderness protection.
Category Ia	Strict Nature Reserve: protected area managed mainly for science.
Category Ib	Wilderness Area: protected area managed mainly for wilderness protection.
Category II	National Park: protected area managed mainly for ecosystem protection and recreation.
Category III	Natural Monument: protected area managed mainly for conservation of specific natural features.
Category IV	Habitat/Species Management Area: protected area managed mainly for conservation through management intervention.
Category V	Protected Landscape/Seascape: protected area managed mainly for landscape/seascape conservation and recreation.
Category VI	Managed Resource Protected Area: protected area managed mainly for the sustainable use of natural ecosystems.

1. A protected area is defined in the new *Guidelines for Protected Area Management Categories* (IUCN 1994b) as: an area of land and/or sea especially dedicated to the protection and maintenance of biological diversity, and of natural and associated cultural resources, and managed through legal or other effective means.

These range from strict nature reserves, managed primarily for scientific research and/or environmental monitoring, to managed resource protected areas, established for the long-term protection and maintenance of biological diversity, as well as providing for the sustainable flow of natural products and services to meet community needs. Within these six generic categories are hundreds of country-specific designations of protected areas, many of which have the potential to provide locations for research and monitoring activities. In addition, there are three international initiatives, namely the World Heritage Convention, UNESCO Man and the Biosphere Programme, and Ramsar Convention, and regional agreements such as ASEAN (Association of Southeast Asian Nations) and the African Convention on the Conservation of Nature and Natural Resources by which natural sites can be designated as being of global and regional importance. Such sites are usually designated for special protection under national arrangements and classified under the IUCN system accordingly (for further details on these see Section 7.3).

The Man and the Biosphere (MAB) Programme, which was launched by UNESCO in 1976 as a global programme of international scientific co-operation dealing with people–environment interactions over the entire range of bioclimatic and geographic situations of the biosphere (Robertson-Vernhes 1993), is of particular interest because of its scale. One of the central tenets of the MAB Programme is the establishment of a global network of biosphere reserves to cover all of the world's major ecosystems, and by January 1994 there were 324 biosphere reserves in 82 countries, covering some 2 115 000 km². The past role and future objectives of this programme were discussed during an International Conference on Biosphere Reserves in Seville, Spain in 1995, which adopted ten key directions as the foundations of the new 'Seville Strategy' to develop its three main functions of conservation, development and logistical support (Seville Strategy for Biosphere Reserves, 1995). This is discussed further in Section 7.3 (also see Box 7.3-6).

At the national and provincial level, considerable progress has been made in completing protected area systems, so that they are representative of major landforms, habitats or ecosystems. For example, in south and south-east Asia the protected sites network has increased by more than 500 new protected areas covering some 130 000 km² since 1982 (McNeely *et al.* 1994); and Canada's federally approved 'Green Plan' has established a target of setting aside 12% of the country as protected space, and completion of the national parks system by the year 2000 (Environment Canada 1991). However, out of the total 8641 protected areas designated, 56% are found in temperate regions of the world (North America 1410, Europe 2245, East Asia 1162), and only 26% in tropical regions. If analysed by surface area similar percentages are

obtained (McNeely *et al.* 1994; see also Section 13.4.2.1.1).

In addition to state administered protected areas, other sites are protected by a range of other measures. These include private or community-based protected areas, private land management agreements and covenants, and sites recognized by local people as having long-term heritage or sacred significance (e.g. Gadgil 1991). In New Zealand, for example, there are about 2000 sites in these categories, many of considerable value for biodiversity conservation, protected as covenants under the Queen Elizabeth II National Trust through voluntary management agreements (Given 1994).

By comparison with terrestrial areas, marine protected areas lag behind in concept, legislation, management and public awareness. The Law of the Sea has given responsibility to each coastal nation for resource conservation within its Exclusive Economic Zone (up to 200 miles from the shore). These coastal-marine ecosystems comprise approximately 30% of the Earth's surface, including 40% of the ocean (Ray and Gregg 1991), yet the world list of National Parks and Protected Areas jointly compiled by IUCN and WCMC (1990), lists only 2200 coastal and strict marine nature reserves, national parks, natural monuments, managed nature reserves/wildlife sanctuaries and protected landscapes. Moreover, fewer than 13% of these were solely marine protected areas (Ray and McCormick-Ray 1994).

It is difficult to assess objectively the effectiveness of the protected area systems as a resource because of the limited documentation available on the organisms present within them. In 1992, the World Conservation Monitoring Centre carried out a study on the Status of Plant and Animal Inventories for Protected Areas in the Tropics (WCMC 1994). Based on a preliminary search of information held at WCMC, the survey revealed that only 5% of the protected areas in the tropics had been inventoried for one or more groups of organisms. The best-recorded groups, in descending order, were birds, mammals, flowering plants, reptiles, amphibians, freshwater fish and butterflies. The study concluded that protected areas in tropical regions are poorly described in terms of their plants and animals, and that the majority of inventories that do exist are of a preliminary not a comprehensive nature. This situation is not peculiar to the tropics: even in Europe and North America no single site has yet been fully inventoried for all organisms present (see Section 7.1.4.2 and Table 7.1-1). This is the aim of the All-Taxa Biodiversity Inventory (ATBI), to be carried out in conjunction with site-based protocols for setting up very large blocks of wildland biodiversity for non-damaging development (Janzen and Hallwachs 1994; see also Section 7.2.9.2 and Box 7.2-5).

The lack of knowledge as to what is already included in protected areas represents a serious limitation in current

attempts to assess the effectiveness of the system both in terms of the species protected and whether or not they are being safeguarded. However, there are two encouraging trends in support of protected area initiatives, particularly in the context of biodiversity assessments. The first is the identification of key data sources and the collation of such materials, particularly through GIS systems (see Sections 7 and 9). This is being accompanied by a move to make such materials more accessible, such as making data sets available through Internet. The second is a process being engaged in by many protected area agencies to identify the type and level of detail of information on indicators which would allow for effective management, monitoring, and non-damaging use (see sections 7 and 13). At the global level, this is resulting in the development of generic data models to collect and manage biodiversity information at the site level (e.g. INBio and Guanacaste ATBI site in Costa Rica; see homepage <http://www.inbio.ac.cr/GCA.ATBI>). Organizations such as the World Conservation Monitoring Centre (WCMC) and the Intergovernmental Oceanographic Commission of UNESCO (IOC 1993), are beginning to give

attention to this development, the former for terrestrial protected areas, the latter for coastal and marine ecosystems.

In addition to protected areas, systems of permanent plots for periodic inventorying are also important for biodiversity assessments. These have been developed, for example, for forests, through the Smithsonian Institution and Man and the Biosphere Programme (Dallmeier 1995; Dallmeier and Comiskey 1995; see also Sections 7.2.2.2 and 7.2.9), and some US initiatives such as the Forest Health Monitoring (FHM), Forest Survey Inventory (FIA), National Resources Inventory (NRI) Plots and remote sensing programmes as discussed by Lund *et al.* (in press).

8.3 General biological reference collections

8.3.1 Introduction

Biological reference collections, and their associated libraries and staff, are the major tools necessary for basic investigation and assessment of biodiversity. Cotterill (1995), for example, considers that ‘The preservation of specimens in natural history collections is the essential part of the process which builds and maintains biological knowledge’. Pressure on collections, however, has resulted

Box 8.3-1: Examples of specimens in natural science collections (Duckworth *et al.* 1993: 20).

baculi/phalli	plaster field jackets; complete dioramas with historical, artistic and scientific value)
blood components	
casts/molds/peels	micromounts
cell suspensions	mummified specimens
cleared and stained specimens	non-recent, sub-fossil material
cloned probes	paraffin blocks
dissected organs and other dissected tissues	pinned specimens
DNA/RNA (including sequence gels)	polished sections
dried/tanned skins	powder diffraction mounts
dry shells or echinoderms	radioactive specimens
educational collections	reference sample collections (hair, feathers)
eggs and nests	scats
embryos/larvae	sectioned teeth
endo- and ectoparasites	seeds
exhibit collections	shell structures
exsiccata	single crystal mounts
fossils	skulls and skeletons
freeze-dried specimens	specimens in fluid (geological, biological)
frozen tissues	specimens in packets or boxes
frozen tissue extracts	specimens or specimen parts on scanning electron microscope stubs
frozen whole specimens	specimens or specimen parts on microscope slides
genomes (plasmid, phage)	stomach contents
herbarium sheets	stuffed specimens
horns/antlers	thin sections
inherently toxic specimens	tree rings and wood samples
isolated proteins	type specimens
karyotypes	zymograms
large specimens (e.g. blue whale skull; large fossils in	

in a ‘second biodiversity crisis’ (McGinley 1993), namely the inundation of museums and other institutions by collections arising from field surveys in a period when their budgets are being reduced or pinned (Culotta 1992).

Biological reference collections constitute the material basis for biodiversity assessments. Such collections comprise permanently preserved specimens, and many other items such as slides made from specimens, recordings and photographs (see Box 8.3-1) maintained in museums, universities, botanic gardens and similar institutions, or by individual scientists. Such collections serve as proof or supporting evidence for the identity of a particular organism, and for the existence of that entity at a certain location at a particular point in time. The collections are ‘anchors’ for all future reference to that entity’s occurrence, include the vouchers for the application of scientific names (i.e. name-bearing ‘type’ specimens), and provide the means for checking the identity of that entity in the future. Additionally, the advent of computerized information handling and manipulation, coupled with molecular technology, means that such reference collections will become strongly supplemented with extensive and permanent recorded observations, images and genetic data.

The value of biological reference collections is considered further in Section 2.1, while in this Section the focus is on the assessment of limitations in relation to their distribution, dimensions, preservation methods and cost-effectiveness.

8.3.2 Distribution and dimensions of biological reference collections

A consequence of the broad range of preserved non-living materials that comprise biological reference collections (Box 8.3-1; Duckworth *et al.* 1993: 20) is that a great deal of thought needs to go into policies for acquiring such material and for resourcing the long-term maintenance necessary.

Duckworth *et al.* (1993) estimate that there are some 2.5 billion specimens in preserved biological reference collections world-wide. The distribution of these is grossly skewed, the vast majority being located in developed countries in temperate regions. The distribution and dimensions of the plant and fungal collections are depicted in Table 8.3-1, and a parallel indication of zoological resources is presented as Table 8.3-2. However, it is

Table 8.3-1: Number of Plant and Fungal Biosystematic Reference Collections (PFBRC) and specimens world-wide (abridged from Holmgren *et al.* 1990).

difficult to assess the value of these collections on a regional or global basis without a database of their actual holdings.

The efficient description of global biodiversity, and the ability to compare material from many regions when assessing whether or not a species has previously been described, requires major concentrations of material which are only likely ever to be maintainable in a few places in the world. All the world's major collections comprise material accrued over extended periods of time, commonly 100 years or more. Such collections cannot be built up rapidly, and presuppose commitments to long-term financing, appropriately trained personnel, and a high degree of communication with the major collections in other countries (Holloway 1983). Nevertheless, significant holdings are being built up in less developed regions; for example, the Natural History Museum of Zimbabwe now holds 5.3 million specimens representing at least 58 200 different species (Cotterill *et al.* 1993).

The value, size and cost of maintenance of biological reference collections has been questioned by some workers in relation to the data that can be obtained from them (Clifford *et al.* 1990), and substantive counter-arguments have been published (Chalmers *et al.* 1990). However, the collections are widely dispersed through numerous institutions and countries, and their value as an overall resource for biodiversity assessments is less than optimal, for the following reasons.

- Collections are rarely located close to the most biodiversity-rich areas where the need for them is greatest in order to support inventorying and monitoring programmes.
- Most collections comprise only certain groups of organisms, those of particular applied or research interests, or material from one country or region.
- Major cities often have several different institutions with collections, each separately financed, controlled by different authorities, and with independent policies.
- The label data they contain are in most cases difficult to access except on a systematic basis as they are rarely computerized and stored in a database and are therefore not readily retrievable by country, locality or ecology.
- Acquisitions policies tend to be inclusive rather than selective which, while appropriate for some collections, can lead to an exponential growth in material, especially of commoner species, which may be too costly to maintain satisfactorily in the longer term.
- Curatorial resources are generally inadequate for the task so that the quality of the collections is

deteriorating through time, and locating specimens and making them available for examination on or off site may be impractical.

- Identifications have not always been revised in line with current research.
- Collections do not always have links with local universities to enable them to optimize their use for education and research.

The methods of preservation (8.3.3), accessibility (8.3.4), and curation standards (8.3.5) of collections are especially important issues, and are therefore highlighted below.

8.3.3 Preservation methods

The diversity of materials held in biological reference collections (Box 8.3-1) requires a range of specialized skills, knowledge and technology to ensure their preservation in a manner that does not reduce their scientific value. This extends to the nature of the materials on or in which specimens are contained or mounted, for example the quality of the paper, glue, slide-sealants and insect mounting pins. Particular care must be taken to ensure that the characters necessary for the confirmation of the identity of the material are adequately preserved. For example, specimens of larger fungi are of limited value if they are preserved in liquids that do not retain the original colour of the fruit-bodies. In the case of microscopic preparations, slide mountants must be stable and carefully prepared so as not to evaporate and render the material almost valueless after ten or more years.

In addition to the manner in which the individual specimens are prepared, the overall storage conditions of the collections must also be adequate. Ideally, this requires the maintenance of low relative humidity and a constant temperature to minimize the probability of the growth of spoilage moulds, and the maintenance of physical security against weather, insects and vertebrate pests (Fosberg and Sachet 1965). Preservation and storage methods have been thoroughly reviewed by Duckworth *et al.* (1993), who include an extensive bibliography. For botanical collections, the various practices are documented by Bridson and Forman (1992).

The methods of preservation also have implications for the usability of specimens for DNA extraction. Appropriately preserved collections are sources for DNA samples (Thomas 1994a) which can yield data relevant to conservation biology, evolution, and medicine as well as biological systematics (Thomas 1994b). For example, studies on DNA extracted from deer ticks in museum collections in the US showed that the Lyme disease bacterium was present in the country for several decades before it was officially recognized (Persing *et al.* 1990).

However, not all material preserved by traditional methods will be suitable for DNA extractions. Examinations of mushroom species of the genus *Agaricus* collected at intervals from 1902 revealed that long chains of DNA begin to deteriorate after between two and six years and that breakdown was almost complete after 33 years of museum storage, although sometimes specimens which had been stored for an equal length of time responded differently. These differences were attributed to temperature fluctuations and other aspects of treatment (Haines and Cooper 1993).

An alternative is to preserve tissue samples separately so that they can be used for DNA studies at a later date. The practice of taking tissue samples is now widely used for birds, and it is estimated that about one-third of the world's bird species have so far been sampled in this way (Arctander and Fjelds  1994; Fjelds  pers. comm.): maintenance at -70°C has been recommended (Thomas 1994b). The extension of this practice will facilitate the future development of DNA libraries (see 8.9). In addition, the DNA-Bank-Net international initiative has been set up recently to represent the interests of a range of institutions interested in collecting and storing plant material for subsequent DNA extraction and utilization, and recommends the maintenance of plant DNA extracts by cryopreservation at -196°C (Adams and Adams 1992).

8.3.4 Accessibility of biological reference collections

Despite improvements in travel and communications, a large proportion of the maintained and documented collections remains accessible only with difficulty to those who most need the information they contain, particularly scientists in the countries from which the specimens were obtained. The databasing of information associated with collections is accelerating, but for the largest collections significant progress is unlikely to occur without special funding for projects designed not only to improve access to the data but also to facilitate the repatriation of information to the countries of origin of the specimens.

As collections do become computerized, they are increasingly making information available world-wide through information servers on the Internet (e.g. Cornell University, gopher address muse.biol.cornell.edu.70; ERIN). Data on around 2 million museum specimen records are now available on the Internet (Miller 1993). The Association of Systematics Collections in the United States has developed a series of data-sharing and transfer guidelines for natural history institutions housing specimen-based databases. These guidelines (Association of Systematic Collections 1993) are flexible, and provide a framework for action within the context of the requirements of countries that have ratified the Convention on Biological Diversity. The number of application systems suitable for the manipulation of name-based data is

expanding, and these are listed on TAXACOM (e-mail address: taxacom@cmsa.berkeley.edu) from time to time.

8.3.5 Collection health

Various factors need to be taken into account in assessing the adequacy of the curation of biological reference collections. The Smithsonian Curation Standards and Profiling System (McGinley 1993), originally developed for entomological collections, has much to commend it as a means of assessing the state of curation of collections generally. This system recognizes ten levels of curation (Box 8.3-2) and, based on the numbers of storage units, a Collection Health Index can be calculated as the sum of units of levels 3 + 6–10 (inclusive) divided by the total number of units. Curation up to level 6, and ideally 7, is necessary for collections to contribute in a substantive way to biodiversity assessments. However, not even all the major world collections presently operate at level 7.

Box 8.3-2: Smithsonian Curation Standards and Profiling Systems (after McGinley 1993).

- LEVEL 1. Conservation problem.
- LEVEL 2. Specimens unidentified, inaccessible.
- LEVEL 3. Specimens unidentified, accessible.
- LEVEL 4. Specimens identified but not integrated into collections.
- LEVEL 5. Specimens identified but curation incomplete.
- LEVEL 6. Specimens identified and properly curated.
- LEVEL 7. Data capture: species level inventory.¹
- LEVEL 8. Data capture: specimen label data captured.
- LEVEL 9. Data capture: research data captured.
- LEVEL 10. Scientific voucher material (including name-bearing types).

1. A list of the scientific names of the species represented.

8.3.6 Costs of biological reference collections

Costs for the care of biological reference collections vary greatly from place to place and among different kinds of collections. There have been only a few attempts to quantify the costs, one of them being in a report published on the systematic botany resources in the United States (Payne *et al.* 1979). There, it was estimated that the cost of a well-prepared, identified, accessioned and inserted herbarium specimen was between US\$6.45 and US\$7.68. It should be borne in mind that these figures were valid about 15 years ago [c. 1980], and they do not include the often considerable costs of collecting the specimens in the first place. However, estimates vary greatly depending on the purpose of the collections and the type of specimens. For instance,

estimates of total collection costs vary from US\$18 per plant specimen in an ethnobotanical study (Halloy 1994b) to US\$26 per plant accession for a collecting trip in South America (Halloy 1990); A\$52.5 has been quoted as the mean cost for the collection and curation of a botanical specimen in Australia (Nielsen and West 1994); and £20 per museum specimen treated, conserved and stored, including staff and materials costs, has been quoted for the UK (Howie 1986). Fossils and large mammals may cost one or two orders of magnitude more than other types of material. However, when, spread over the useful ‘life’ of specimens, which extends forward indefinitely, this initial cost is not high compared with annual maintenance costs.

More generally, *Systematics Agenda* 2000 (1994) estimated that the cost of the current annual global level of research and infrastructural support for systematic biology, including support for collections, is about US\$500 million.

The economic cost-benefits of investments in biological reference collections are difficult to quantify, but the ability of the world to reap the benefits of a greater understanding of biodiversity will be in some direct proportion to the investment in its documentation and study. The costs of establishing, maintaining and increasing accessibility to specimens and data held in reference collections will be an integral component of proposals to realize the full potential of Earth’s biodiversity resource, although there is still debate as to whether support for the service roles of collections could be to the detriment of the vitality of systematics as a scientific discipline (Renner and Ricklefs 1994a, b; but see also Minelli 1994; Beattie 1994; Cotterill *et al.* 1994; Rejmánek *et al.* 1994; Pine 1994).

8.4 Information resources

8.4.1 Libraries

With few exceptions, the great library and document collections of the disciplines that contribute to biodiversity are in the developed world. They exist within the museums, learned societies, research institutions, and botanical and zoological gardens of Europe, North America and Asia. Historically, these collections owe their existence to the determination of the societies in which they are located to fund their continued existence. By their very nature, collections of paper-based information require large amounts of space, secure buildings, trained staff and controlled temperature/humidity conditions or controls that avoid extremes. The countries that have been able to provide these conditions have restricted their locations to the great cities of the developed world. For new information, electronic media mean that dependence on paper materials will become of decreasing importance.

The conditions that led to the world’s major biological document collections being in the developed world are still pertinent, although in recent years, major libraries have

been started in the developing world. The institutes of the Consultative Group for International Agricultural Research (CGIAR) provide a good example: adequate funding has enabled a large library on livestock to be set up at the International Livestock Centre for Africa (ILCA) in Addis Ababa, and one on Insect Physiology and Ecology (ICIPE) has been established in Nairobi (Fisher *et al.* 1990). Advances in technology, for example the suites of abstracts and other data on CD-ROM (see below) and also on-line services, have meant that it is now less important for extensive library holdings to be duplicated in many centres, especially as this technology can be linked to rapid document-delivery services.

The critical importance of new technology delivery systems is apparent from the number of journal titles potentially containing information relating to biodiversity. A search of ULRICH'S International Periodical Directory on-line (DIALOG file 480, Bowker) gives 12 982 titles for the words 'biology', 'botany', 'agriculture' and 'zoology' and their variants. An extensive search of the same database to select titles that indicate that they would contain articles on 'biodiversity' retrieved over 2400 titles. Such numbers strain the budget of even well-funded libraries, and also occupy huge amounts of space. Libraries are finite in space, and the expansion of journal titles forces on them the labour-intensive business of near-constant stock disposal exercises. This policy is deleterious when applied to biosystematic literature, which has an extended shelf-life, original descriptions and inventory lists being of lasting significance. Indeed, it is the location of and access to literature from the nineteenth and early twentieth centuries, representing major periods of documentation of tropical biotas, that is especially difficult for researchers from developing countries.

8.4.2 Electronic media

The publishing of whole databases on CD-ROMs has enabled users of biological information around the globe to have access to large bibliographic files in a relatively inexpensive and user-friendly format (see Section 9). At the time of writing, a vast range of relevant titles is available in CD-ROM format, including the CAB ABSTRACTS database (and subsets thereof), *Biological Abstracts* (BIOSIS) and *Index Kewensis*. The discs themselves are small and light, apparently long-lasting and not palatable to insects, and while the costs are high for databases that need to recover the costs of data compilation, these can be funded by donor agencies. The equipment needed to use them is a PC equipped with a CD-ROM drive, and it is expected that most PCs will be fitted with the drive as standard within a few years.

In addition to bibliographic databases and indices, primary titles are now appearing in CD-ROM format. For example, the Compact International Agricultural Research

Library is a 17-disc CD-ROM set covering selected materials from 20 international agricultural research centres located in 16 countries. It covers documents published between 1962 and 1986. Some journal titles are now available in parallel formats with the printed copy, giving a more easily transported and durable copy of the information to the world, as in the case of the *Florida Entomologist* and the *International Journal of Systematic Bacteriology*.

Systematic databases for a range of different taxonomic groups are now also available on floppy discs, such as the *Bacterial Nomenclature Up-to-Date* issued once a year by the DSM-Deutsche Sammlung von Mikroorganismen und Zellkulturen GmbH, and many others available through the Internet. However, they vary enormously in the scope, quality and completeness of the information provided, and are not free from inconsistencies and disparities caused, for example, by the use of different systematic treatments of the same group. A co-ordinated effort is required to standardize the content of and access to this information, and this has led to the idea of the preparation of a world species checklist under the programme *Species 2000* (Bisby 1994; see also 8.4.4 and Section 2.1).

The phenomenal growth of the Internet, the world-wide link-up of computer networks and users, continues the trend set by CD-ROM in making possible the bringing of information to the user rather than the other way round. E-mail users across the world can send messages to each other at very low cost, and can also attach text files. Technically, the results of a CD-ROM or on-line search can be transferred between e-mail addresses, although this may contravene intellectual property (copyright) legislation (see Section 9). The number of users with access to the Internet expanded at the rate of 10% per month during 1993, and currently stands at around 29 million. The Biodiversity Information Network (BIN) on Internet, operated from Brazil (Canhos *et al.* 1992), has been developed to end the isolation of many workers in the field. The possibilities of new forms of accessibility, and also their cost-effectiveness, mean that it will increasingly be a question not of the technology limiting the delivery of information into developing countries that will be the bottleneck (Miller 1994), but rather the costs of putting the required material into machine-readable formats. Some of the problems and misconceptions relating to biodiversity information are analysed by Allkin and Winfield (1993), Fortuner (1993), and Shetler (1973). Careful planning, quality control and sustained management are prerequisites for effective computer-based information systems.

8.4.3 Directories of biodiversity information

For assistance in locating sources of information on species, their habitats and genetic resources, as well as international catalogues and indexing services (see also 8.4.4), various annotated directories are available. The

directories of plant germplasm collections list the germplasm holdings of specific crops and food plants in institutes around the world including root and tuber crops, cereals, vegetables, industrial crops, tropical and subtropical fruits and tree nuts, temperate fruits and tree nuts and forages. The information in many of the directories serves to aid scientists and policy-makers in steering them to more detailed sources of information, and helps them to make contact with other individuals working in the area of interest (see Box 8.4-1).

8.4.4 Catalogues, indexes and registers for described species

The fundamental element in communicating about organismal biodiversity is the names of the organisms themselves. Therefore catalogues must be produced not only of all the described species names, but also of their correct names according to the appropriate nomenclatural Code (8.10.3) and according to the latest research into their relationships and position in the taxonomic phylogenetic system. The lack of a comprehensive synthesis means that it is impossible to provide an answer, with any degree of certainty, to the question ‘How many species are known on Earth?’ The difficulties encountered in arriving at the working figure for known species of 1.75 million are discussed in Section 3.1.2.2.

The main compilations of names (Box 8.1-1) comprise a mixture of catalogues (mostly from the last century) and on-going indices, but these do not exist for all groups of organisms. In addition, detailed catalogues for particular groups are published occasionally. At present, with the exception of bacteria published since 1980, a person describing a new species is under no obligation to register that name with any authority. The International Registration Authorities for the ‘cultivar’ names of cultivated plants operate only as a voluntary system, and no Authorities exist for many genera. However, registration has been approved for names in all ‘botanical’ groups from the year 2000, subject to details of the mechanisms to be drawn up by the International Association for Plant Taxonomy (Greuter *et al.* 1994), and the concept is also under discussion for the next edition of the Code concerning names in zoology (Hawksworth *et al.* 1994). The establishment of funding mechanisms will be crucial to the realization of comprehensive registration systems.

The current compilations of names, and also registers of names, are nomenclatural devices rather than a continuously updated list of scientifically accepted species with the ‘correct’ name. It is such global master species databases that are the real need of those involved in the inventorying, description, communication and regulation of biodiversity and its uses. This type of information does exist for many (but not all) groups, but it is uncoordinated and scattered though a variety of databases located in

Box 8.4-1: Selected directories useful for biodiversity information.

different countries (Bisby 1993). With advances in computing and communications technology, it is now technically feasible to consider putting the many existing data sets together so as to prepare a draft single master-species database covering all groups of organisms.

That such a major compilation could now be achievable is indicated by two recent events: first, the production of a list of 28 041 generic names for non-fossil botanical groups

prepared with the help of over 200 plant systematists (Greuter *et al.* 1993); and second, the establishment of a mechanism to produce a list of the accepted species of the world's vascular plants (Burnett 1994).

In recognition of the international need for a global synthesis of the organisms now known on Earth, in September 1994 the 25th General Assembly of IUBS unanimously agreed to include the production of a global master species database in its scientific programme. Preparation of a costed proposal for the project 'Species 2000: A world species index' is now under way with the support of CODATA and IUMS. This database would be one of the crucial tools needed by the Clearing House Mechanism to be established under the Convention on Biological Diversity (see Section 9). Once it was established, the database could be updated through links to the proposed on-going registration systems for newly proposed names (see above).

8.4.5 Identification aids

The range of available field guides, keys and other identification aids is a major constraint to the assessment of biodiversity. Further, these need to be in local languages and well illustrated to be of optimal value to reserve managers and other non-specialists charged with inventorying and monitoring activities. With the major exception of field guides to birds, and in some cases also other vertebrates and flowering plants,¹ even countries in Europe (Sims *et al.* 1988) and North America lack a comprehensive set of such works.

Several useful ideas for the preparation of user-friendly identification keys have resulted from the work of the 'Aids to Identification in Difficult Groups of Animals and Plants' (AIDGAP) project, an initiative of the Field Studies Council, Great Britain, the main objective of which is to 'promote alternative ways of presenting aids to identification'. The project highlighted the need for the extensive use of illustrations, which improve the accuracy of identifications, conspicuous characters, and the testing of identification keys before publication (Tilling 1987). However, this was attempted with only a limited number of groups, and these were chosen from well-studied and documented organisms. Further information on different presentation methods, e.g. single- and multi-access keys, were outlined by Tilling (1984), but both types have their advantages and disadvantages. New initiatives such as computer-based identification aids will play an increasing role, such as those prepared in CD-ROM format by the Expert-Center for Taxonomic Identification (ETI), Amsterdam (see also Section 2.1).

1. On-line information on these on subject and countries can be obtained from the Natural History Books Service Catalogue, available on <http://www.nhds.co.uk>

8.5 Living plant collections

8.5.1 Types of living plant collection

Living plant collections comprise those held in botanic gardens, national collection gardens, special plant collections, parks, special amenity collections, roadside plantings and arboreta. They are important in the assessment of biodiversity because the extent of morphological, genetic and chemical variation within plant species can often be adequately researched only by examination of living material from a range of locations. They also have a significant role in conservation biology and in practical conservation. In some cases they may also serve as genetic resource collections, as relatively secure *ex situ* locations for threatened or valuable species, and sometimes even species which are extinct in the wild. Unlike biological reference collections, living plant collections have a continuous turnover, as species are lost and newly collected ones are introduced (Buttel 1992; Halloy 1995). Two general concerns that apply to all living plant collections are: (1) that the genetic variation within the species is often grossly under-represented, and (2) that those genotypes best suited to the conditions of cultivation may be selected for (Hurka 1994; Given 1994).

8.5.2 Botanic garden and arboretum collections

8.5.2.1 What is a botanic garden?

Botanic gardens, in the sense of collections of living plants grown for some educational, economic, medicinal or scientific purpose, have played a significant role in many civilizations and cultures over the ages. However, there is no universally accepted or entirely satisfactory definition of a botanic garden (Heywood 1987; WWF and IUCN-BGCS 1989), and this complicates the making of assessments as to their overall adequacy or contributions. Most botanic gardens are broadly based botanical resource centres that undertake work in a variety of botanical disciplines of which conservation is an important part, and Heywood (1987) proposed a subdivision into categories related to their origins and functions: for example, European Medicinal, European Classical, Colonial Tropical, and Civic and Municipal. However, the following characteristics are shared by most gardens.

- They maintain documented living plant collections.
- They are open to the public and provide educational information on their collections for visitors.
- They undertake scientific or horticultural research.
- Their plant collections are labelled.
- Their collections are amassed for purposes other than decoration and amenity, and are often of documented wild origin, valuable for scientific and conservation purposes.

Table 8.5-1: Number of botanic gardens world-wide (Information compiled by Botanic Gardens Conservation International).

i.e. Number of taxa reported in cultivation in the Botanic Gardens.
1. Includes species, subspecies, varieties and cultivars.

Most botanic gardens do not have sufficient technical resources to be able to achieve much effective conservation and research into biodiversity. Nevertheless, their developing role in conservation and education has provided many with a new rationale for existence and the last decade has been a renaissance period for the international botanic garden community.

In 1989, *The Botanic Gardens Conservation Strategy* (WWF and IUCN-BGCS 1989) was published to outline the role of botanic gardens in living resource conservation and in the implementation of the World Conservation Strategy. This strategy is now used by many institutions to help guide their development. Complementary to the strategy, a series of technical publications is being produced by organizations such as Botanic Gardens Conservation International and the Center for Plant

Conservation, USA to guide specific aspects of botanic garden conservation programmes. Manuals for botanic gardens have been published or are in preparation on the subjects of *ex situ* conservation, seed banking, reintroductions and species recovery, the Convention on International Trade in Endangered Species of Wild Flora and Fauna (CITES), environmental education and plant data management.

8.5.2.2 *The extent, distribution and resources of botanic gardens*

There are almost 1600 botanic gardens and arboreta world-wide, although this number is dependent on how such gardens are defined (8.5.2.1). While the majority of these gardens are located in Europe and North America (see Table 8.5-1), there are relatively few countries in the world without any botanic gardens. The early European botanic gardens were centres for the study of properties of plants used in medicine and pharmacy (Heywood 1987, 1990). In

the last twenty years, many new botanic gardens and arboreta have been created, primarily for the conservation, management and utilization of plant diversity and for environmental education. Many older botanic gardens established before this century, especially those created by the major European colonial powers in many tropical countries and regions, were founded to introduce and grow plants of economic importance. Some of these gardens, for example those in Brazil, the Caribbean, India, Indonesia, Singapore and Sri Lanka, are now being redeveloped or reorganized to undertake new roles in the conservation of plant genetic resources as part of their mission. Other well-established botanic gardens in many countries are reviewing their purposes and facilities through the preparation of new strategic and corporate plans, mission statements and collections policies, and in general, most botanic gardens have now put more emphasis on the conservation of native plants than on introduced plants.

There is a serious geographical imbalance of botanic gardens in the world. In Europe and North America there are many more botanic gardens than in developing regions of the world: 431 were listed for North America alone by Watson *et al.* (1993). Furthermore, most botanic gardens in developing countries are amongst the most poorly resourced and many lack sufficient trained or experienced staff. Nevertheless, BGCI currently estimates that there are in the region of 800 botanic gardens active in some significant form in biodiversity conservation, although the extent and effectiveness of each varies enormously, from those involved in small-scale local actions to those undertaking major international programmes.

8.5.2.3 Botanic garden networks and linkages

An important feature of the botanic garden scene between 1985 and 1995 has been the extent to which networks of closely co-operating botanic gardens have been developed. In 1987, IUCN established the Botanic Gardens Conservation Secretariat (BGCS) to unite and promote the role of botanic gardens in plant conservation. In 1990, BGCS became independent (as Botanic Gardens Conservation International (BGCI)) and has grown to include over 400 member institutions in more than 80 countries.

During the same period several important national and regional botanic garden networks have been established or developed. Botanic gardens are further linked through the International Association of Botanical Gardens (IABG), founded in 1956 and a commission of IUBS. IABG has active regional divisions in Latin America, East Asia and Europe. National botanic garden organizations exist in many countries such as Australia, Brazil, China, Colombia, Cuba, France, Indonesia, Japan, Republic of Korea, Mexico, Netherlands, the Russian Federation, South Africa, Spain and Portugal. Although these networks have arisen

from a great diversity of origins there is now close co-operation between them.

The American Association of Botanical Gardens and Arboreta (AABGA) acts as an umbrella organization for North American public gardens and is increasingly considering biodiversity conservation as part of its mission. In addition, in the USA a national network of botanic gardens active in plant conservation operates through the Center for Plant Conservation (CPC), based at the Missouri Botanical Garden, St Louis. CPC includes over 20 leading gardens and manages a national collection of rare and endangered native plants conserved *ex situ*. In 1993 and 1994, BGCI signed co-operative agreements with other major organizations such as IABG and AABGA to help draw together the leading botanic garden networks.

8.5.2.4 What plants are in botanic garden collections?

The total number of accessions of taxa held in botanic gardens is not less than 3.2 million (cf. Table 8.5-1). Allowing for unregistered collections, BGCI estimates that there are currently more than 4 million living plant accessions maintained in botanic gardens, representing in the region of 80 000 species. This represents about 30% of the known species of flowering plants and ferns and 25% of those estimated for the world (Table 3.1-2). Many species are not represented by a sufficient range of accessions to reflect adequately the genetic variation within the species in their normal ecological context (see 8.5.1). The limited genetic diversity held of native species and uncertainty over optimal horticultural practices can contribute to failures to maintain them (Hall and Rycroft 1979).

The international database maintained by BGCI has already documented holdings of 250 000 accessions and includes records from over 350 institutions, representing about 30 000 species (Leadley *et al.* 1993).

Documentation of garden collections is, however, still inadequate in many institutions. A BGCI survey carried out in 1993 on plant recording methods in botanic gardens revealed that only 76 (7.3%) definitely had computerized systems in operation, although that could be an underestimate as only 117 responded to the survey. However, many others intimated that they planned to computerize their recording systems within the next few years. Most botanic gardens also have poor knowledge of and access to technical assistance in computerization although a number of standard plant recording software systems are now available to them, as well as an agreed international standard for data exchange, the International Transfer Format for Botanic Garden Plant Records (BGCI 1993).

The plant groups best represented in botanic garden collections are those of horticultural or other economic interest such as carnivorous plants, orchids, palms, cacti

and other succulents, woody legumes, ferns, cycads, bulbous plants, bromeliads and conifers. Many botanic gardens place particular emphasis on growing and maintaining, thematic collections of such groups as medicinal and aromatic plants, economic plants, particularly fruit trees and their wild relatives, ornamentals, plants of ethnobotanical or historical interest, alpinists and temperate or tropical trees. A list of botanic gardens specializing in medicinal plants or with special collections of them is given by Heywood (1991a).

Data held by BGCI indicate that the floras of many major tropical and sub-tropical continental countries, such as Brazil, Colombia, Indonesia and Zaire, as well as others, especially in Africa and South America, are poorly represented in botanic garden collections. Better represented are the floras of Europe, North America, temperate South America and Asia, Australia and New Zealand and South Africa. In most of these regions as much as 30% of their rare and endangered flora is known to be represented in cultivation by at least a few individuals per species. Also well represented are the endemic floras of many oceanic island groups, especially Macronesia, the Mascarene Islands and Hawaii.

A recent trend is for botanic gardens to focus on and give priority to the cultivation of the native flora of their own region, particularly those that are threatened, which will add significantly to the scientific value as well as the conservation value of the resource. However, the long-term future of threatened cultivated species may be less secure due to lack of genetic diversity in the small samples of natural populations, as well as problems of cultivation (Hall and Ryofft 1979).

8.5.2.5 Conservation programmes

The diverse range of botanic gardens world-wide has allowed the emergence and development of a wide range of conservation programmes, resources, skills and experience, although many of these are still in very early stages of development (He Shan-an *et al.* 1990; Heywood 1992, 1993a). Their *ex situ* conservation activities include:

- Maintenance of living collections which include representatives of many rare and endangered species.
- Gene banks, especially seed storage facilities.
- Specialized nurseries and horticultural centres.
- Propagation and bulking up of material for re-introduction programmes.
- Micropropagation and tissue culture.

In addition, some botanic gardens have important non-living reference collections associated with them and a

considerable number are focal points for systematic research, contributing to the understanding of biodiversity through floristic and biosystematic study. The BGCI database lists 721 botanic gardens with associated herbaria containing, between them, over 80 million specimens. Botanical research in many other pertinent fields can be undertaken, including ethnobiology, horticulture, conservation biology, population biology, ecology, molecular botany and genetics.

Botanic gardens also have a role in protecting ecosystems. Over 500 botanic gardens either contain areas of natural vegetation or have such areas directly under their control. This provides opportunities to undertake extensive *in situ* conservation action. Many of these gardens, and other institutions, work with protected area managers or agencies to contribute to the management of *in situ* plant resources.

8.5.2.6 Further sources of information

Further information on botanic gardens and their role as a resource for the assessment of biodiversity and its conservation is provided in the following publications: Akeroyd *et al.* (1994), Akeroyd and Wyse Jackson (1995), WWF and IUCN-BGCS (1989), Bramwell *et al.* (1987), Bramwell and Heywood (in press), Butler *et al.* (1992), Chauvet and Delmas (1991), Falk (1990), Falk and Holsinger (1991), Froggatt and Oates (1993), Given (1994), Hamann (1992), He *et al.* (1990), Hernandez-Bermejo *et al.* (1990), Heywood (1991b), Heywood *et al.* (1990), Heywood and Wyse Jackson (1991), Larsen *et al.* (1989), Richardson *et al.* (1991), Suhirman *et al.* (1994), WCMC (1992), Willison and Greene (1994), Willison and Wyse Jackson (1992).

8.5.3 National plant collections

National plant collections are samples of plants of particular genera, or other groups of species, grown in a particular country which are brought together in private or public gardens. They constitute a data gathering, cataloguing and exchange facility network of small plant collections acting as a support web. They are very diverse in composition and location, and can be an additional research resource. Although large numbers of collections remain in private hands, others are held by botanic gardens, nurseries, corporations, colleges and universities. In addition to the intrinsic and historic value of such collections, they often contain plants that are endangered in their natural habitat, and therefore it is important that these plants are conserved. National collections may, in conjunction with other bodies, assist with re-introductions to the wild.

Well established nationally and internationally is the UK National Council for the Conservation of Plants and Gardens (NCCPG), with over 600 collections, covering 13 000 species and 39 000 cultivars (Greenoak 1994). Similar initiatives have been established in Australia

(Australian National Plant Conservation Network, ANPC; Ornamental Plant Collection Association, OPCA), France (Conservatoire des Collections Végétales Spécialisées, CCVS), North America (Center for Plant Conservation; North American Plant Preservation Council; North American Plant Collection Consortium) and more recently in New Zealand, associated with the Royal New Zealand Institute of Horticulture. These organizations produce, on a regular basis, catalogues containing information on size (number of species and cultivars), locations and accessibility of collections (NCCPG 1994).

8.6 Zoological gardens, insectaries and aquaria

Zoological gardens, aquaria and insect-exhibiting facilities, like botanic gardens, have historically had a range of purposes in different cultures and countries but are now developing a unified role in conservation and education. This is exemplified by the publication, in 1993, of The World Zoo Conservation Strategy (IUDZG/CBSG (IUCN/SSC)), which outlines the ways in which zoos and aquaria can contribute to the conservation of the Earth’s wildlife and biodiversity and their role in the implementation of the World Conservation Strategy. In particular, zoos maintain *ex situ* many animals which are highly endangered in the wild and the captive specimens may represent an important part of the remaining gene pool of these species. Co-ordinated breeding programmes, with the long-term aim of supplementing wild populations, or re-introducing populations, will play an increasing role in zoo strategy. *Ex situ* living collections of

invertebrates, fish and tetrapods established for conservation purposes also have value as a resource for the study of the biodiversity of the species maintained, at both the genetic and organismal levels (see Section 13.4.3.3 for further analysis of *ex situ* conservation in zoos).

World-wide, there are probably more than 2000 zoological gardens, aquaria and insect-exhibiting facilities: 1996 are noted in Table 8.6-1, and further information on 1787 of these is included in the *Global Zoo Directory* (1993). Of these, roughly 1000 mostly publicly owned facilities have joined national or regional zoological associations. Approximately 800 of these routinely reply to the annual surveys of the *International Zoo Yearbook*, are typically professionally managed, and constitute most of the informally ‘recognized’ zoos of the world. Nearly 500 are now actively linked as members of the global International Species Information System (ISIS) network – which is expanding at about 40 institutions per year. Through ISIS, member facilities share detailed biological information on hundreds of thousands of specimens.

These zoological gardens and other facilities hold a combined live animal population of more than 700 000 tetrapods (201 000 of which are now registered in detail through ISIS). The facilities also hold an estimated 600 000 fish, and an unknown number of invertebrates. Collections registered with ISIS contain 341 species of amphibians, 1275 species of reptiles, 3101 species of birds, and 1189 species of mammals.

Based on the recent *Global Zoo Directory* (1993), the more developed regions of the world (North America, Europe,

Australasia, Japan) have 1157 zoological facilities – roughly two-thirds of the total, with Latin America, Asia outside Japan, and Africa having a total of 630 presently known. Africa, whose megafauna has pride of place in many zoo collections, has only about 30 zoos. While statistics are not yet available, zoos in the developing regions probably exhibit proportionately more native wildlife, rather than exotics. This is often beneficial – developing local awareness and pride in the local or national fauna, which many people might otherwise never see.

Assessment and monitoring of their collective holdings and the status of captive populations is accomplished in three ways – through the *International Zoo Yearbook* (IZY), the International Species Information System (ISIS), and ‘studbooks’ (see Section 7.3.5.6). IZY provides articles on zoological science management, and surveys some 878 zoos annually – tabulating information on the inventory and captive breeding of notable species. ISIS is an international non-profit membership network, with 499 member facilities at present (from 54 countries on six continents) which share detailed biological information via computers on more than 200 000 living specimens and more than 550 000 of their ancestors, covering 5800 species. Nearly 400 taxa are monitored even more intensively by the same number of volunteer studbook-keepers, who assemble and publish the most complete data possible for their taxon.

8.7 Marine stations

8.7.1 Marine stations and the marine realm

Marine stations are seaside laboratories with a long history of biological and ecological research. In contrast to other major biodiversity resources, marine stations are relatively evenly distributed among tropical, temperate and cold latitudes and between the major coastal ecosystems. Their common culture and traditions, which have predisposed them to co-operative programmes (Lasserre *et al.* 1994), combined with the ease of accessibility of their biological research materials, have encouraged a tradition of high quality descriptive and experimental research.

The marine stations of the world have great potential as an infrastructure for programmes in research, training and education, and conservation of marine biological diversity. Marine stations are usually closely tied to academic institutions or museums with long-standing traditions in the study of marine organisms, in the training of scientists and managers, in communication and exchange with other marine stations, and in environmental impact assessments. Many are government supported with strong mandates in resources management.

There are five areas of research in which marine stations have made a unique contribution: (1) the use of marine organisms as models in developmental biology, molecular biology and genetics, biotechnology, neurobiology and pharmacology; (2) the long history of inventorying and

monitoring all types of marine organisms, forming a firm basis on which to build a comprehensive study of biogeographic gradients in biological diversity; (3) the special facilities that have been developed to study aspects of biodiversity experimentally, ranging from the molecular level to experiments on natural communities in the marine environment; (4) evaluating fish stocks and assisting in developing strategic policies to strengthen the fishing economy in developing countries; and (5) providing the infrastructure both to respond rapidly to unexpected events and to study the biological effects of longer-term environmental change.

8.7.2 Marine stations as biodiversity observatories

The marine stations are ideally placed for inventorying and monitoring marine and coastal biodiversity in terms of their facilities, expertise, long data sets and geographical location (Grassle *et al.* 1991). Outside the deep sea sediments, which support an immensely rich biota (Grassle 1991; 3.1.2.2), the coastal zone has been the major source of novel discoveries in marine biodiversity since the end of the nineteenth century. Historically, marine research stations have played a very important role in such discoveries and many marine stations have published inventories which describe the distribution patterns of marine species to some degree. Most of them have reference collections of local marine fauna and flora, and many of them are well equipped to study delicate forms of pelagic organisms (including gelatinous plankton, picoplankton, ciliates, bacteria and viruses) and benthic taxa (bacteria, ciliates and fungi, meiofauna and macrofauna and the larval stages of all kinds of marine species).

The continuity of research in the vicinity of marine stations has led to the assembly of long-term data sets which form a critical baseline against which human impact may be assessed (Lasserre *et al.* 1994). These data sets are a critical resource for monitoring marine biodiversity, and cataloguing, standardizing and comparing them is a key challenge being undertaken by marine station networks.

8.7.3 Existing networks

A number of regional networks have been formed to co-ordinate biodiversity research in marine stations. These networks, discussed in detail in Section 7.3.3.3, aim to cover the coastal ecosystems by a chain of marine observatories which would exchange their long-term time-series data and develop initiatives to encourage a better use of existing data sets. The objectives are to:

- identify the long-term data sets available in marine stations in order to establish which processes, communities, and variables are best represented, and to highlight where there is a paucity of data that

would recommend the initiation of collections of other long-term data sets;

- design comparative studies that combine the information contained in these data sets to answer relevant questions that transcend the local scenario of the data sets;
- identify constraints to the comparability of these data sets to: (a) modify and standardize sampling procedures; and (b) recognize the methods best suited to compare different data sets;
- develop initiatives to encourage use of existing data sets (e.g. foster an adequate forum for comparative analyses of the data sets, promote intercalibration exercises, improve the availability of the data sets).

8.8 Genetic resource collections

8.8.1 What are genetic resource collections?

A genetic resource collection is a repository of samples of living material of animals, plants, fungi or microorganisms, generally in a dormant or other phase in which they are not actively growing, which have been assembled for use in breeding and for other purposes. The collections encompass stores of gametes, pollen, seeds, spores, tissue cultures and embryos maintained in long-term storage facilities. Material that does not lend itself to such 'dormant' storage can be maintained in field gene banks, as in the case of some cultivated plants (IPGRI 1993; Eberhart *et al.* 1991). Although botanic and zoological gardens and similar types of collections largely maintain material that is actively growing and reproducing ('living collections', 8.5 and 8.6), these institutions are increasingly also housing 'dormant' material.

Although DNA extracts, DNA or RNA sequences, or even a genetic map, could be considered genetic resources, at present they cannot be used to reconstitute the whole organism from which they were derived and are therefore considered separately in this Section (8.3.3 and 8.9).

The organisms in genetic resource collections are predominantly representatives of taxa currently farmed, cultivated or cultured by humans, or the wild relatives of these taxa. In the case of fungi and other microorganisms, because of the difficulties of making fresh isolations from nature, genetic resource collections are a major, and in some cases the only, source of material both for biodiversity studies and for screening for potentially exploitable properties. In the case of bacteria, and from 1993 also certain eukaryotes (such as fungi and microalgae), living strains permanently preserved in such collections also serve as the name-bearing type specimens.

When living organisms are domesticated, cultured,

cultivated or husbanded, people assume responsibility for sheltering them to some degree from the natural evolutionary forces of natural selection and genetic drift. Since the rates of unwanted selection and genetic drift depend on the number of generations per unit time, dormancy, enhanced by cryopreservation techniques, is a vital component of the management of genetic resource collections in keeping these rates low. This is particularly so since the distinct breeds, landraces, strains and cultivars which have been created by artificial selection are usually able to interbreed with each other and, if they escape from collections, can interbreed with their natural relatives, losing some or all of their special characteristics and reverting to the wild (when they are known as feral) or becoming weeds (see also Section 3.1.4). Genetic resource collections are thus especially important as the only practical option for the long-term maintenance of domesticated genetic diversity.

8.8.2 Management of genetic resource collections

Genetic resource collections are assembled to ensure the conservation of genetic diversity, to provide a source of material for its characterization and evaluation and to make it available for distribution and utilization. They also provide a source of material for the characterization and evaluation of the variation present within a species or genus. It is therefore essential that adequate stocks are conserved, and that these are regularly monitored and updated, both to ensure this availability into the foreseeable future and to maintain the genetic integrity of the material.

In all cases, both taxa and individual accessions must be clearly defined and separately catalogued. Relevant information about the origin of individual accessions and their properties needs to be documented and made available with the germplasm accessions. The samples are most appropriately characterized on the basis of known DNA sequence information rather than phenotype information. This provides both a more comprehensive coverage of existing diversity, and may also provide the means to avoid duplication (redundancy) of germplasm collections. In this context, especially in the case of microbial collections, the use of molecular markers, such as those obtained from DNA fingerprinting and RFLP techniques (see Section 2.2), is very valuable, as has been shown for the collection of cassava germplasm by Beeching *et al.* (1993; see also Section 10.1.1.1), and provides a powerful approach for investigating the genetic basis of variation between different varieties and for manipulating complex genomes.

Genetic resources can be conserved *in situ* (maintained in their original habitat and reproducing within the environment in which they evolved and continue to do so) or *ex situ* (maintained outside their habitats, stored in a reproductively dormant condition). If *in situ*, they may be

Box 8.8-1: The Consultative Group on International Agricultural Research (CGIAR): the agricultural research centres network (data from CGIAR 1992).

- *Centro Internacional de Agricultura Tropical* [International Centre for Tropical Agriculture] (CIAT): Germplasm holdings of *Phaseolus* spp. (44 558 accessions); *Manihot esculenta* (5532), and tropical pastures (2001).
- *Centre for International Forestry Research* (CIFOR): Germplasm holdings of woody species.
- *Centro Internacional de Mejoramiento de Maíz y Trigo* [International Maize and Wheat Improvement Centre] (CIMMYT): Germplasm holdings of maize (11 150 accessions), wheat (73 794) *Triticale* (13 268), barley (7991) and rye (194).
- *Centro Internacional de la Papa* [International Potato Centre] (CIP): Germplasm holdings of potato (5455 accessions), sweet potato (5753), and other Andean roots and tubers (468).
- *International Centre for Agricultural Research in Dry Areas* (ICARDA): Germplasm holdings of cereals (47 907 accessions), food legumes (20 091) and forages (19 771).
- *International Centre for Research in Agroforestry* (ICRAF): Germplasm holdings of agroforestry species such as *Grevillea robusta*, *Pentaclethra* spp. *Sesbania* spp. and *Milettia* spp.
- *International Crops Research Institute for Semi-Arid Tropics* (ICRISAT): Germplasm holdings of sorghum (33 108 accessions), millets (29 254), chickpea (16 442), pigeonpea (11 910) and groundnut (13 158).
- *International Institute of Tropical Agriculture* (IITA): Germplasm holdings of sweet potato (1000 accessions), cassava (1704), yams (2250), *Musa* spp. (440), taro (60), wild *Vigna* (1620), soybean (1500), cowpea (15 185), rice (12 355), Bambara groundnut (2000), etc.
- *International Livestock Centre for Africa* (ILCA): Germplasm holdings of browse plants (1629 accessions), grasses (2863), and legumes (6860).
- *International Network for the Improvement of Banana and Plantain* (INIBAP): Germplasm holdings of *Musa* spp. (1032 accessions).
- *International Plant Genetic Resources Institute* (IPGRI) [formerly International Board for Plant Genetic Resources (IBPGR)]: an autonomous international scientific organization whose mandate is to advance the conservation and use of genetic resources.
- *International Rice Research Institute* (IRRI): Germplasm holdings of *Oryza sativa* (74 000 accessions), *O. glaberrima* (2300), wild species and species hybrids (1900), and taxa related to *Oryza* (20).
- *West Africa Rice Development Association* (WARDA): Germplasm holdings of rice (8500 accessions).

artificially maintained as in the case of farmers' fields or managed to some degree as in the case of protected areas (see Section 13.4).

8.8.3 Types of genetic resource collection

Plant genetic resource collections include seed samples, spore samples, pollen samples, field-grown material ('field gene banks') for clonally propagated species such as tuber crops or those with recalcitrant seeds (seeds which do not lend themselves to desiccation and storage at low temperatures) (Table 13.4-4) and *in vitro* collections, as embryos, tissues or cell suspensions (National Research Council 1993; Hinton 1994).

Animal genetic resource collections include embryos and semen under cryogenic storage, groups of living animals kept under supervision in an exclusive area, or networks of breeding groups linked by administrative measures, legal restrictions and financial incentives, such as pedigree registers (Table 13.4-4).

Genetic resource collections of microbial groups comprise cultures of algae, bacteria, fungi (including lichen-forming species and yeasts), protozoa and viruses, as

well as material derived from them in the form of cDNA, plasmids, vectors, cell lines, and genetically engineered organisms. These collections have historically been referred to as 'culture collections', but as their role is identical to that of other genetic resource collections it is most appropriate to consider them as particular categories of genetic resource collections (Hawksworth 1995a).

8.8.4 Content of existing genetic resource collections

8.8.4.1 Plant genetic resources

World-wide, over 150 major crop gene banks are held by international, regional and national institutions, both public and private. Leading international germplasm collections for the major food crops have been established mainly in the International Agricultural Research Centres (IARCs) by the Consultative Group on International Agricultural Research (CGIAR) (Box 8.8-1). Collectively, these centres hold the largest *ex situ* collection in the world with some 510 000 accessions (about 10% of the total holdings), but this is believed to correspond to approximately 35% of all accessions held in *ex situ* collections (FAO 1994). Regional gene banks include the Nordic Gene Bank and the Southern

¹Note: Number of collections is not necessarily equivalent to number of gene banks in a given country.

African Development Community (SADC) Gene Bank while examples of national gene banks are those of CENARGEN (Brazil), CSIRO (Australia), the National Bureau of Plant Genetic Resources (India), the Plant Genetic Resources Centre (Ethiopia), the M.I. Vavilov Institute of Plant Industry (Russia) and the United States Plant Germ Plasm System (Plucknett *et al.* 1987, Appendix 2).

The CGIAR International Agricultural Research Centres concentrate on land races and cultivars of particular crops and their wild relatives while the storage of seed and other propagules of wild plants is the primary focus of most botanic garden gene banks. There are also some specialist seed banks, such as the one for taxa of the *Brassica* family (Heywood 1992).

The extant world plant germplasm collections together hold some 4.51 million accessions, but these are mainly of agricultural crop cultivars and landraces (Table 8.8-1). While this number may at first appear large, about 3 million of the accessions relate to only around 100 species (Holden *et al.* 1993), most housed at the specialist CGIAR International Centers (Plucknett *et al.* 1987). They do not therefore represent an adequate sample of even the world's utilized plants. A more detailed breakdown of some of the accessions and their coverage is given in Table 3.1-6.

Recognition that the sheer size of a germplasm collection could militate against its use led Frankel (1984) to propose the notion that it could be pruned to form a 'core collection'. This can be defined as 'a limited set of accessions derived from an existing germplasm collection, chosen to include as much as possible of its genetic diversity'. A review of 'core collections' is given by Hodgkin *et al.* (1995).

The current system of germplasm collections (mainly seed banks) does not provide an adequate representation of the world's flora. Fewer than 1% of the world's plant species comprise more than 60% of the accessions (Halloy 1990). If the number of species of utility to humans is considered, the situation is also far from satisfactory. As an illustration of this, the Plant Resources Project of South-East Asia (PROSEA) records over 8000 species in its basic list of species used by humankind in that area (Lemmens *et al.* 1989) and assuming that similar percentages of the floras of other regions are similarly employed, Heywood (1993b) has extrapolated a figure of 25 000–30 000 species for the tropics as a whole. In addition, several thousand species are used by humans in temperate regions of the world and many thousands of species are grown for ornament in parks, in public and private gardens, and as street trees. Up to 25 000 species have been used in traditional medicines. Huxley and Westley (1989) consider that 2000 woody species are of value to humans. Vietmeyer (1990) estimated that around 20 000 species are edible by humans world-wide, of which 3000 are regularly used. If this figure is accepted, it would mean that existing gene banks contain a mere 0.5% of the species actually used by humans as food. Addressing this situation in an adequate way would be an enormous undertaking, especially as so many accessions are necessary, at least in the case of crop varieties, to reflect adequately the genetic variation in domesticated species. For example, although there are 333 413 accessions of rice *Oryza sativa* (WCMC 1992), they still do not cover all the land races that the International Rice Research Institute (IRRI) would ideally wish to safeguard. Just how much genetic variation in wild species

Table 8.8-2: World animal genetic resource collections. This table presents the numbers of indigenous breeds of the main mammalian livestock species (ass, water buffalo, cattle, goat, horse, pig and sheep: WCMC 1992; Hall and Ruane 1993) with an indication from an incomplete survey of the literature by SJGH, of the nature of the genetic resource collections for these species in the respective countries. Note that water buffalo and cattle are combined, and ass and horse. Poultry includes waterfowl and turkeys. An entry in the table indicates that in the respective country there is some conservation activity for one or more indigenous breeds. Abbreviations:

- G Government station conserving, evaluating or multiplying
- N Other government organization or large NGO concerning itself with indigenous breeds (includes universities, charities, environmental organizations)
- P Established and long-term conservation mainly in private sector
- B Breed society normally operating herdbook, flockbook, studbook or pedigree register
- I Legal or financial inducement or restriction aimed at supporting indigenous breed
- F Feral population either protected or not
- C Cryogenic conservation of semen and/or embryos

Notes: For the pairs Czech and Slovak Republics, Democratic People’s Republic of Korea and Republic of Korea, Eritrea and Ethiopia, the numbers of native breeds are for the two countries combined and the genetic resource collections are detailed for each country separately. The entry for France includes French overseas territories

This table has been compiled from the following sources: Alderson (1990), Basile (1992), Burke (1988), Chapuis *et al.* (1994), Clarke and Dzieciolowski (1991), Coblenz (1990), Corbet and Harris (1991), Crawford (1990a,b), Groombridge (1992), Hall and Ruane (1993), Henson (1992), Hodges (1992), Hone (1990), Katyega (1987), Loftus and Scherf (1993), Macfarlane (1993), Melgar *et al.* (1985), Ministère de l’Agriculture et de la Pêche (1992), Mukai *et al.* (1989), Muñoz and Tejon (1986), O’Uigin and Cunningham (1990), Rege and Lipner (1992), Rodriguez and Martinez (1992), Simon and Buchenauer (1993), Weiner (1990).

should be stored is a matter that has not yet been resolved.

Although 528 botanic gardens and arboreta report having a seed bank, many are poorly constituted and are probably little more than a seed handling facility without a capacity for more than short-term seed storage. Many seed facilities in botanic gardens still operate only to allow them to participate in the international seed exchange scheme between botanic gardens. In a survey undertaken between 1985 and 1990 by BGCS, 144 botanic gardens reported having a low-temperature seed storage facility. Guidelines for the management of seed collections by botanic gardens are being prepared by the Center for Plant Conservation and ANZECC.

Pollen, unlike seed, is not a conventional means of germplasm storage and the main use of stored pollen has been in plant breeding to facilitate hybridization between plants that flower at different times.

Information on plant tissue culture collections is often incorporated with those of microbial collections and included in microbial databases (see 8.8.4.3). In 1992, 29 botanic gardens were known to have opened tissue culture units. These units are being used both for plant propagation and for tissue storage. Many new tissue culture facilities are being opened annually in botanic gardens. A network of such facilities operates, linked by the *Botanic Gardens Micropropagation Newsletter*, which is published twice a year by the Royal Botanic Gardens, Kew, in association with BGCI. The International Plant Propagation Society founded in 1951 also publishes material on micropropagation. An analysis of botanic garden seed lists in recent years indicated that 432 (of 600 from 25 countries) contained wild-collected seeds.

8.8.4.2 Livestock

Of the species of mammals, other vertebrates and invertebrates kept by humans (Mason 1984; WCMC 1992), only about 40 species are important in their daily existence and very few are represented in genetic resource collections. Large sectors of animal husbandry do not have any such collections. Many local breeds of dog are endangered (e.g. Brisbin 1989) and there are no genetic resource collections backing up the farming of deer and other game species (Boyazoglu and Hetényi 1994). There are only a few genetic resource collections of local wild populations of salmon (*Salmo salar*) from different rivers in Norway and Iceland, and farmed stocks are cryogenically conserved in national sperm banks (Gausen 1993). Conservation of old honeybee (*Apis* spp.) stocks seems to be practised only by the prohibition of the keeping of other varieties within defined areas; bees of the old European black type are protected in this way in Australia (Ruttner 1976), and the Bashkir bee in the Russian Federation likewise (Petrov 1980). At least one

strain of laboratory mice is conserved as frozen embryos (AICR 1991).

In several countries one or more of the indigenous breeds of livestock are represented in genetic resource collections, organized in ways which reflect the livestock traditions of that country. Hardly any such collections include material from other countries. The only exceptions are stocks of semen or embryos, belonging to livestock development companies or organizations, which are imported for the development of local breeds. These stocks are therefore not to be seen as fostering genetic conservation *per se*, but rather as functioning in a parallel manner to the CGIAR institutes for crop plants (see Table 8.8-2 and Table 3.1-8 which summarizes the *World Watch List for Domestic Animal Diversity*, published by FAO/UNEP (1993), which lists 2800 breeds for seven domestic livestock species).

8.8.4.3 Fungi and other microorganisms

Microbial collections include strains which are important for both biosystematics and human utilization. However, they must expand their scope considerably if they are adequately to represent all microbial groups. At present the World Data Centre for Microorganisms (WDCM), established under the aegis of the World Federation for Culture Collections (WFCC) and sponsored by UNEP, UNESCO and RIKEN, holds a database on 786 328 microorganism strains held by 482 collections from 58 countries: 44% are fungi (including yeasts), 43% bacteria, 2% viruses, 1% live cells and 10% others (i.e. plasmids, plant cells and algae; Smith and Hawksworth in press; Sugawara *et al.* 1993; Table 8.8-3). Further, 35% of all strains are held by only ten collections.

As, with a few exceptions, cultures of bacteria have to be deposited in collections as a requirement for valid publication of the name (Lapage *et al.* 1992), we have by definition almost 100% coverage for the 3100 known species. However, that figure has to be seen in the context of the huge numbers of bacteria that are undescribed and uncultured (Table 3.1-2). In the case of the fungi, it has been estimated that in 1990 the collections registered with the World Data Centre for Microorganisms collectively held about 11 500 species, around 17% of those then described, and fewer than 1% of those estimated to occur (Hawksworth 1991a). The proportion of described species in culture collections is likely to decrease with time as of the 1700 or so fungi newly described each year, about 70% are not cultured.

Extensive genetic variation occurs within fungi and other microorganisms. Biological species occur within many already cultured fungal 'species' (Brasier 1987; see Section 3.1), and numerous genetic variants are known of others – over 3000 in the case of the sexually reproducing *Neurospora crassa* (Fungal Genetics Stock Center 1988).

1. Totals do not allow for synonymy and also include infraspecific taxa.
2. Accurate information known only from Zimbabwe.
3. Subtotal excludes the names of bacteria and fungi in the collections from the countries of the former Soviet Union.

A parallel situation occurs in clonal (mitosporic) fungi, and bacteria; for example, some 1500 serological variants of *Salmonella* are held by the International *Salmonella* Center and 6000 of *Escherichia coli* in the *E. coli* Genetic Stock Centre (Bachmann 1988).

An increasing amount of data pertinent to bacterial systematics and collections in particular are now available through electronic networks and databases; Canhos *et al.* (1993) list eight electronic networks, nine information resources, and 23 computerized databases (see 8.4).

The World Federation for Culture Collections (WFCC) coordinates the activities of culture collections. The WDCM was established within this framework, and presently holds on-line information on the strains maintained. Detailed information on these strains is offered to the public through catalogues, published periodically by most of the major culture collections (Sugawara *et al.* 1993). There are other organizations at regional and international levels, such as the European Culture Collection Organization (ECCO), Microbial Strain Data Network (MSDN), and the Microbial Resource Centres (MIRCENs), information about these can be found in Hawksworth and Kirsop (1988) and Smith and Hawksworth (in press).

8.8.5 Constraints

The major constraints to the formation, adequate management and use of genetic resources collections, as discussed in more detail in Cohen *et al.* (1991), are:

- Shortage of trained people to collect and classify.
- Poor understanding, in many cases, of the genetics and population biology of the taxa in question.
- Lack of basic biological knowledge on species and their variability.
- Lack of appropriate techniques for long-term preservation.
- Lack of secure funding and funding mechanisms, especially in the long term.
- Poor awareness of the strategic and long-term value of genetic resource collections among policy makers, researchers and potential users.
- Increasing social and political barriers to collection and exchange, as expressed by variety rights and patents, and legislation to restrict movements of species across borders
- Poor social awareness of conservation issues.

8.8.6 The development of genetic resource collections

8.8.6.1 Plants

Future priorities for assembling plant genetic resource collections include:

- Assessment of the biodiversity already available within existing collections and identification and prioritization of missing or under represented species, geographic regions and environments.
- Development of improved management methods for long-term secure conservation, including the maintenance of genetic integrity.
- Use of existing collections as part of sustainable development.
- Determination of which segments of biodiversity are best conserved *in situ* in wildland areas.

Although collections of some of the world's major crops are extensive, and relatively secure, the situation for many other crop and tree gene pools is far less satisfactory. For example, Clement (1991) stressed the need for further research in the field of perennial crops – principally fruit trees – domesticated or semi-domesticated by indigenous people of Western Amazonia. Whilst well-known species, such as cassava (*Manihot esculenta*), pineapple (*Ananas comosus*), rubber (*Hevea* spp.), papaya (*Carica papaya*), cacao (*Theobroma cacao*), and brazil-nut (*Bertholletia excelsa*) have *ex situ* and *in situ* collections, many others are little known outside the region, but contain significant genetic diversity and are unrepresented in the collections. For a major review of tropical forests and their crops, see Smith *et al.* (1992).

There are still gaps in the range of accessions of both land races and wild relations of crop species, and in many collections not all accessions are well documented. Valuable collections are not always adequately regenerated or multiplied, and Buttel (1992) considers that a large proportion of genetic resources in crop seed banks are dead – a statement in need of critical evaluation. Material may also not be available because of insufficient quality or quantity, and unwarranted replication of accessions between and within collections can hinder their effectiveness. Greater international co-ordination of botanic garden seed banks is required as well as information on their holdings which are still inadequately known.

Also, there is a need for further research into the technology of germplasm conservation and experimental testing of techniques. Conservation efforts have barely begun for a wide range of species (IPGRI 1993). Genetic diversity needs to be measured, both in the field and in germplasm already conserved, and further research is

needed to design optimum conservation strategies (Center for Plant Conservation 1991; Brown and Schoen 1994).

8.8.6.2 *Livestock and other animals*

The priorities for animal genetic resource collections include:

- The making of inventories of livestock and other domesticated animals in areas that have not been fully documented (e.g. Africa).
- The strengthening of protection of breeds in areas that have been surveyed but where greater protection is needed (notably the former Soviet Union and China).
- Taking account of the need to conserve local breeds in livestock development projects, especially in those countries with indigenous breeds.
- The establishing of genetic resource collections for the many sectors of animal agriculture that do not have them (see 8.8.2).

Conservation of rare breeds could be facilitated by requiring that all relevant stock improvement proposals supply a 'genetic impact statement' (Hall 1992). If the development is likely to damage the genetic integrity of local breeds, then conservation of the latter must be assured.

8.8.6.3 *Fungi and other microorganisms*

The future priorities for microbial genetic resource collections should be to:

- Capture a greater proportion of the microbial gene pool in world collections by long-term cryopreservation methods in order to safeguard their genetic potential. This work should begin with collection of material from disappearing habitats.
- Improve collaboration between and strengthen the present network of 482 collections within the World Federation for Culture Collections to maximize complementarity.
- Consider how to establish a framework similar to that co-ordinated by IPGRI for plant genetic resources.
- Develop methods for quality control of the collections.
- Develop new techniques to culture and preserve hitherto uncultured strains and strains from extreme conditions.

The World Federation for Culture Collections (WFCC) has prepared guidelines for the establishment and operation of microbial collections (Hawksworth 1990; Kirsop and Hawksworth 1994).

8.9 Sequence databanks

Molecular techniques and databases offer a means to survey and quantify biodiversity through the acquisition, storage and analysis of linear sequences of amino acids and nucleotides. As has been seen in earlier Sections of the GBA, molecular sequence studies of DNA, RNA and proteins are powerful tools, and in some cases the only ones available, for biosystematic analysis, biodiversity surveying, and quantification and conservation.

Molecular databases are held in the developed countries of the northern hemisphere, with access typically free via the Internet and through CD-ROM subscriptions (but see Section 9 for a discussion of the problems of accessing data on human, livestock and crop plant gene sequences). The principal molecular databases are listed in Box 8.9-1. There are two groups: nucleic acid sequence (DNA and/or RNA sequences) repositories and protein (amino acid) sequence repositories. World-wide there are three primary databases that collect and distribute nucleic acid sequences: GenBank, EMBL and the DNA Data Bank of Japan (DDBJ). These databases exchange and update data on a daily basis. The major protein databases are the PIR-International Protein Sequence Database and the SWISS-PROT protein sequence database. To make molecular databases useful for measures of biodiversity, resources must be allocated to ensure that electronic access is easy and affordable.

Databases often contain supporting documentation and software tools for the manipulation and analysis of molecular sequences. For example, the National Center for Biotechnology Information at the National Library of Medicine in the US supports Nentrez (via the Internet) and Entrez (on CD-ROMs). Both provide access to nucleic acid and protein databases and offer links to a literature citation database, MEDLINE. A variety of tools exists for retrieving sequences according to keywords, authors, and organism names amongst others. A recently announced feature of Nentrez and Entrez is the ability to use classification hierarchies to extract sequences. Ultimately the biosystematic mode will accommodate alternative phylogenetic perspectives in the search procedures. Although biosystematic information has always been available in molecular databases, such as EMBL and GenBank, the ability to search and sort sequences according to taxonomic rank represents a step forward in making molecular databases useful for studies of biodiversity.

Box 8.9-1: Molecular sequence database.

<i>Specialized Protein Databases</i>		
PROSITE (protein function and structure)	Geneva, Switzerland	datalib@embl-heidelberg.de
<i>Note:</i> Access to and information about the RDP can be obtained by sending e-mail or making an ‘anonymous ftp’ connection to: info.mcs.anl.gov (140.221.10.1). Change directory to pub/RDP and get the 000README.ALL file. In addition to the data, RDP services are available by electronic mail. Further information is available by sending to rdp@mcs.anl.gov a single line e-mail message with the word: Help.		
Additional information about molecular databases can be obtained from the database issue of the journal <i>Nucleic Acid Research</i> 21 : 2963–3156 (1993).		

The lack of attention paid until recently to the role of taxonomic information in molecular databases is also reflected in other ways. One of the most problematic is that there is no obligation for scientists depositing sequence data in databanks to preserve voucher material simultaneously when the organisms are preservable. A consequence of this policy is that it is not always possible to re-check identifications when divergent sequence data are lodged for the same species. In the long-term interests of data quality, the practice of making it mandatory for depositors to deposit vouchers in service genetic resource collections should be encouraged wherever possible.

Most molecular data exist as individual sequence submissions to databases such as EMBL, GenBank or SWISS-PROT. For example more than 500 chloroplast ribulose-bisphosphate carboxylase gene coding region sequences have been deposited in GenBank. They have been used to measure the diversity of plant chloroplast genomes and to reconstruct the evolutionary history of plants (Chase *et al.* 1993). An even larger database used to infer phylogenetic relationships is the collection of more than 2000 small subunit ribosomal RNAs (ribonucleic acids), commonly referred to as 16S, 18S, 16S-like or SSU rRNA sequences. These sequences have gained widespread

acceptance among systematic biologists for inferring relationships at all levels of the taxonomic hierarchy, from above the kingdom to below the species, and are therefore an extremely powerful means of measuring and understanding organismal biodiversity (see Section 2.1). Though the number of major groups that have no representative members within the rRNA dataset continues to shrink, there remain major gaps in our knowledge, particularly of eukaryotic microorganisms.

The contribution of macromolecular (nucleic acid and protein) sequences in assessments of biodiversity, as well as any inferences of phylogenetic relationships, is contingent upon the ability to align homologous positions between macromolecules of varying length. Unlike archival databases, sequence alignments represent dynamic data structures that change significantly in response to the addition of new information. In general, databases such as EMBL and GenBank do not maintain alignment information for homologous sequences (sequence alignments can be submitted to or retrieved from these databases but only in a static, archival form). Ribosomal RNAs are a notable exception: complete ribosomal sequences can be retrieved in aligned format from the Ribosomal RNA DataBase Project (RDP), which updates its alignments at regular intervals (see note at end of Box 8.9-1). The RDP is a curated database that incorporates new information into a multiple sequence alignment for the 5S, 16S-like and 23S-like ribosomal RNAs. It is maintained at the University of Illinois with a grant from the National Science Foundation. Through e-mail and FTP servers, the RDP offers aligned and phylogenetically ordered rRNA sequences in a variety of user-selected formats, as well as various software programs for handling and analysis of data. In addition, services are provided such as automated sequence alignment, probe design checking, user-selected subsets of the sequence data with corresponding phylogenetic trees, and rRNA secondary structures. This database is of central importance to studies of molecular systematics, molecular structural analysis, and organism detection and identification.

8.10 Human resources

Crucial to the capacity of countries to undertake the monitoring and assessment of the magnitude of biodiversity is the availability of personnel, something governed by both training and funds for employment. The size and distribution of the existing human resource now deployed in systematics is a key constraint which will restrict the ability of countries to fulfil their obligations under the Convention on Biological Diversity, especially under Article 7. The need for urgent action to address this situation has been highlighted in, for example, *Systematics Agenda 2000* (1994).

8.10.1 The magnitude of the resource

8.10.1.1 Systematists

Minelli (1993) speculated that there were 20 000–30 000 systematists working world-wide, but these figures were not based on any data set (Minelli, pers. comm.). For North America, based on scaled-up returns of about 2500 questionnaires, an estimate of 8000–10 000 taxonomists was reached by Edwards *et al.* (1985). Another approach was taken by Stuessy (1993) who analysed society membership lists, staff lists for herbaria, and other sources, to derive an estimate of 1000–2000 ‘active working plant taxonomists in the world’.

None of the above estimates adopted an unambiguous definition of a systematist or taxonomist, including curators, technicians and identifiers, as well as those generating classifications. One objective measure of the workforce available to describe new species is the number of persons actually publishing them in a 12-month period. Analyses of the principal nomenclatural databases, commissioned for the GBA, revealed that during 1991–2, almost 7000 taxonomists described 20 723 species as new to science in a 12-month period (Table 8.10-1). This figure of 7000 is likely to be an underestimate of the total number of active biosystematists on Earth as: not all biosystematists describe species new to science every year; data for algae and bryophytes were not available; there will be some omissions from the indexing databases; and authors with the same surname and initials will have been counted as one person. However, the total does include those who work only on fossils, which account for one-third of the new names now being introduced in zoology. This fact alone gives a figure of 1735 systematists, and more than compensates for the above four points. In view of these considerations, the figure of 7000 is considered as a reasonable approximation of the human resource potentially available to describe new species found in inventory programmes.

Many factors affect the ‘productivity’ of particular scientists in terms of the number of new species they describe in a year, of which the proportion of their time that can be devoted to taxonomy is critical. As discussed below, Janzen (1993) observed ‘that the bulk of good taxonomists today are spending only 0–20% of their time actually doing taxonomy’, a figure from which few of the profession would dissent. Using the 20% figure on the 7000 estimate yields a mere 1400 full-time equivalents, which is clearly inadequate for the task at hand. However, it should also be borne in mind that there is pool of trained systematists who have never found employment in the field: while currently following other careers, they could be available to compete for new positions.

With respect to the workforce, retired professionals merit particular attention, as systematists tend to become more productive with age as their experience of both their chosen groups and the literature accrues. For example, the botanist T.G. Tutin described more species after he reached age 60 years than at any time since he was under 30 (J. Parnell, unpubl.).

Table 8.10-1: The numbers of new species of organisms described as new to science in 1992 compared with the number of authors involved and the numbers of known and estimated species.

Organisms ¹	Species ²	Authors	Species per author		
			1992	Known ³	Estimated ⁴
Viruses ⁵	100	75	3	53	5 333
Bacteria ⁶	120	336	0.4	12	1 190
Fungi ⁷	1 600	498	3.2	141	3 012
Plants ⁸	1 705	875	2	309	366
Animals ⁹	17 218	5 205	3.3	254	1 883
Totals	20 743	6 989	3	250 ¹⁰	1 949 ¹⁰

1. Treated in groups as indexed by the sources indicated; they include fossils in the case of fungi and animals but omit algae and bryophytes as they are not indexed annually.
2. Only newly described species are considered; supra- and infraspecific taxa, transfers between genera, and changes in rank are excluded.
- 3–4. Data from Table 3.1-2.
5. Data supplied by M.A. Mayo (International Committee on Taxonomy of Viruses).
6. From the International Journal of Systematic Bacteriology, extracted by G.S. Saddler.
7. *Index of Fungi* database, extracted by P.M. Kirk.
8. Index Kewensis database, extracted by R.A. Davies.
9. Zoological Record database, extracted by M.N. Dadd and covering the period July 1991 to June 1992.
10. These ratios are based on the total for all groups given in Table 3.1-2, i.e. including algae and bryophytes but excluding fossils.

8.10.1.2 ‘Amateurs’

The distinction between amateur and professional is perhaps less important in relation to the study of biodiversity than in most other fields of science (Bates 1951). Indeed a significant proportion of the species known on Earth have been described by amateurs working to high scientific standards. The critical study of natural history by amateurs was commonplace in Victorian times in the UK (Allen 1976), and the tradition has continued to this day. Flowering plants and birds are especially popular, and attract the largest followings, but the amateur workforce is also significant for butterflies and moths, beetles, larger and lichenized fungi, and bryophytes. As an example, The Royal Society for the Protection of Birds (the UK partner of BirdLife International) currently has 860 000 members, a figure which exceeds the memberships of the three major political parties in the UK.

Hard information is difficult to secure, and the proportion of amateurs included in the numbers of systematists in the analysis in Table 8.10-1 is unknown. The emergence of a skilled amateur workforce is related to the amount of leisure time in society, and it is unlikely to become a major factor in any but the most developed countries. Nevertheless, the amateur is an important part of the human resource able to undertake

systematic work in developed countries, not least because such persons are often able to devote a larger proportion of their time to their studies than many ‘professionals’ (see 8.10.2).

Many amateurs are excellent identifiers, but most are not taxonomists in that they do not provide descriptions of new species or prepare monographic accounts. Not being linked to institutions, amateurs are invariably widely distributed geographically in a country and their collective expertise and location enables them to make particularly significant contributions to distributional studies. In the British Isles, most of the major surveys developed since grid-mapping became established in the 1950s have been possible only by the mobilization of that resource. The *Atlas of the British Flora* published in 1962 had inputs from some 1500 primarily amateur participants (Allen 1986). Atlases of bird distributions, now available for at least 12 countries, also rely heavily on amateur inputs.

8.10.1.3 Parataxonomists

An innovative approach aimed at maximizing the skills of professional taxonomists has been developed at the Instituto Nacional de Biodiversidad (INBio) in Costa Rica since 1986, and has also been utilized by WWF in its

programmes in Madagascar. This involves the use of local rural adults as 'parataxonomists' – persons trained to collect, sort and prepare material for subsequent examination by taxonomists (Janzen 1991, 1992, 1993; Janzen *et al.* 1993). This scheme has been applied particularly to insects and appears to have worked well in Costa Rica. The model merits consideration for application in both other groups and other places.

8.10.1.4 Indigenous peoples

Indigenous peoples without formal scientific training are generally dependant on their biodiversity to varying degrees and need to be able to recognize and communicate about species of value for food, medicine, clothing, construction, weaving, dyeing and other uses, as well as about those that are poisonous or harmful to humans, their crops, or their buildings. An immense amount of precision, as measured against modern species concepts, is to be found in some indigenous peoples' naming systems (Mayr 1969; see Section 2.1.0.1). Where the selection of landraces of crops suited to local conditions has occurred, individual genetic variants with specific useful characteristics may be named and may be important for the breeding of improved cultivars. The fine level of distinction achievable is illustrated by traditional weavers of the Maoris of New Zealand, who recognize over 80 genetically and geographically distinct forms of New Zealand flax (*Phormium cookianum* and *P. tenax*; Given and Harris 1994). For further examples see Table 2.1-2; Berlin (1992) and Berlin *et al.* (1974).

The capture and utilization of this specialist ethnobiological knowledge, and its relation to the scientific database, is an important aspect of biodiversity exploration. This is especially so as some tribal groups and their cultures are themselves dying out, and further because much relevant information is held now only by their more aged members as products of the modern age supersede the traditional at the village level. While significant progress has been made in relation to medicinal plants and land races of crops, only a fraction of that which exists has so far been documented. This is time-consuming work which requires personnel familiar with local languages and dialects who will be trusted by the indigenous peoples being visited. Nevertheless, it is appropriate to accord the capture of such indigenous knowledge priority (Wightman *et al.* 1992, Smith *et al.* 1993). These issues are considered further in Section 13.1.4.2.

8.10.2 The deployment of the resource

8.10.2.1 Geographic deployment

Only about 6% of the world's scientists live in those countries that house 80% of the Earth's terrestrial biodiversity (Systematics Agenda 2000 1994). Although an

overall geographical analysis of the world's taxonomic workforce is not available, there is no reason to assume that this statistic does not apply to those able to contribute to the understanding of biodiversity at all levels. In the case of entomology, the pattern of loans from the Natural History Museum in London indicates that 80% of insect systematists in institutions able to receive such material are based in Europe and North America (Gaston and May 1992). This statistic is probably applicable to all groups of organisms.

However, the geographic deployment pattern is changing, albeit slowly. National and regional facilities staffed by local scientists now exist in many less developed countries, but these are rarely adequately resourced so that immediate service duties rather than taxonomic research are the norm. Especially encouraging are the numbers of scientists and journals concerned with systematics in the broadest sense now located in and produced by such countries. Conversely, the number of taxonomists in at least some former colonial powers is in decline (see Section 7.4.3.2).

8.10.2.2 Subject deployment

Gaston and May (1992) drew attention to the mismatch between the numbers of taxonomists working on particular groups, and the sizes of those groups, drawing particularly on data from Australia and North America. Table 8.10-1 presented here provides evidence that this mismatch occurs on a global scale.

Using the working figures adopted in Table 3.1-2, the ratio of the number of scientists describing new species to the number of known and described species is greatest in the flowering plants (1:309) and least in the bacteria (1:12). The higher ratio for plants than animals (1:254) will reflect the major imbalances within zoology between vertebrates and other groups documented in Gaston and May (1992); for example in Australia they reported that there were 17 tetrapods for each tetrapod taxonomist, but 840 insects and spiders for each entomologist. The mismatches are, however, most striking in relation to the numbers of estimated species where the lowest ratio by far is for plants (1:366) and the greatest figures are for fungi (1:3012) and viruses (1:5333); the situation for bacteria could, however, easily be the largest if some of the more recent estimates of 3 million or more bacteria on Earth are accepted.

The conclusion that fungi and other microbial groups, and also species-rich groups such as insects and nematodes, are grossly under-resourced in terms of the biosystematic workforce compared to other groups is inescapable. Such statistics merit careful consideration when considering the development of national action programmes for biodiversity assessments, and plans for completing the overall inventory as proposed in *Systematics Agenda 2000* (1994), as well as when conducting *All-Taxa Biodiversity Inventories* (Janzen and Hallwachs 1994).

Figure 8.10-1: The coverage of taxonomy in the *Biological Abstracts* BIOSIS database 1969–92 (based on data extracted from the database by M.N. Dadd in March 1994).

8.10.3 Productivity and working practices

8.10.3.1 Productivity

Three measurable indicators of the productivity of the taxonomic workforce are the numbers of scientific papers published, the numbers of new species described, and the time taken to complete major works. A fourth indicator would be the number of species treated (i.e. described, reviewed, revised, illustrated), but a method of obtaining that information on a world-wide scale has not yet been developed.

An analysis of the papers abstracted in the *Biological Abstracts* database BIOSIS, from its inception in 1969 to 1992, shows almost a doubling in the number of systematic titles in the broadest sense. At the end of this period they stood at about 38 000 each year (Figure 8.10-1). The marked rise from 1985 may to a large extent be attributed to the rapid growth of biochemical and molecular systematics and phylogenetics (see Section 2.1). The number of core taxonomic papers, that is those including descriptions, revisions, monographs or new taxa, has also doubled over the same period, but at around 10 000 papers each year is only slightly more than a quarter of the overall systematics output. The existing workforce, especially as it

has been declining in numbers in developed countries (see Section 7.4.3.2), is to be commended on this achievement. However, with respect to the challenge of the time necessary to complete the description of life on Earth, it is of concern that, despite new technologies, the number of papers including new taxa has remained almost unchanged through the last 25 years (Figure 8.10-1).

If there are 11.9 million species still to be described on Earth, at the 1992 rate of description (Table 8.10-1) that task would take another 575 years, i.e. until the year 2570. However, that calculation assumes that the workforce could be directed to the most species-rich groups, and that palaeontologists could be turned into neontologists. Without major shifts in the spending of scientific research monies even such far off dates will not be realizable. In practice, increased prioritization will be necessary, especially for the most species-rich groups (Hawksworth and Ritchie 1993), as even if substantial funding were made available, a sufficient cadre of adequately skilled specialists could not be generated in under a decade.

The data presented in Table 8.10-1 also reveal considerable differences in overall productivity between biosystematists describing new species in different groups

of organisms. Assessed on the basis of the number of species described, mycologists and zoologists appear to be able to describe about 30% more species in a year than botanists. Bacteriologists would appear to have the lowest output, although this is an oversimplification as the mean number of authors of a new bacterial name introduced in 1992 was 5, with a maximum of 12. This is a direct reflection of the wide range of biochemical and molecular data now required formally to describe a new bacterium.

The time taken to complete major botanical works has been investigated by Polhill (1990), who compared the production rates of major regional floras. He found that the rate at which species descriptions were published ranged from 138 (*Flora Malesiana*) to 770 (*Flora Europaea*) each year. While the progress in such projects will to a large degree be directly related to the resources deployed and the editorial policy of the publication, he notes that completion dates are often still distant after many years of work; for example, the *Flora of Southern Africa* started in 1966 is projected to take to the year 2124 (19 500 species; 158 years), the *Flora of Tropical East Africa* started in 1949 and is projected to 2013 (10 500 species; 64 years), and *Flora Neotropica* started in 1968 is projected to 2397 (90 000 species; 429 years). There are parallel examples in other subject areas: the *Handbooks for the Identification of British Insects* series started publication in 1949 but to date has treated only 6000 of the 22 000 insects known in the UK.

Ng (1990) points out that in preparing their work, systematists carry an often unappreciated psychological load. Scientists in most disciplines are concerned over the approval or disapproval of their endeavours by their peers, but systematists are especially conscious of the long-term implications of their work. Acceptably published names, once introduced into the literature, cannot be revoked and will have to be handled in some manner by succeeding generations. No other scientific discipline burdens the literature of the future in such a manner.

Cullen (1984) estimated that 90% of the work published by systematists was for the consumption of other systematists. The need to identify their various target audiences and prepare and deliver works appropriate to those needs in a timely manner has been a concern of several distinguished botanists, including Corner (1946), Heywood (1983, 1988) and Walters (1988). It has been argued that systematists need to view themselves as a part of a retail process, delivering products to customers (Bisby 1984). This is something that will necessitate the adoption of different working practices.

8.10.3.2 Improving working practices

The available systematics workforce needs to increase its effectiveness if it is to meet the challenges of adequately assessing biodiversity. The situation can be improved, but

not alleviated, by taking full advantage of the latest technologies and a re-examination of current working practices is urgently needed. For example, Huhtinen (1994) has provided insights into how data capture may be maximized at the points of collection and examination in discomycete fungi, and the results disseminated more efficiently by modern technology.

The professional systematist of the 1990s spends only a small proportion of the available time on research. This figure has been estimated at 0–20% (8.10.1.1). Increased pressure on a diminishing workforce in developed countries has meant that those with systematic skills have become increasingly involved in data management, curation, preparation and dispatch of loans, identification, editing, refereeing, teaching and consultancies, or in administration or management. In order to improve productivity against such a background, attention must be given to ensuring that the time available for scientific work is used to maximum effect.

A comprehensive and readily accessible catalogue of accepted names (see 8.1.4.1) and their synonyms would be particularly time-saving. In many groups of organisms even finding out what species have been named is far from straightforward. In the case of botanical groups alone, the number of names at species rank, excluding fossils, has been estimated at 1 675 000 (Hawksworth and Greuter 1989). Taking the number of known species in these groups at 320 000 (Table 3.1-2), that suggests 5.2 names have been proposed for each species. An analysis of 15 fungal monographs gave a ratio between accepted names and those having to be evaluated of 1:6.5 (Hawksworth 1992).

The scientific names of organisms are controlled by a series of five internationally agreed Codes or Rules of Nomenclature, each relating to a different organism group (see Section 2.1). While a carefully controlled system is essential, the application of some of the current codes is far from straightforward. The emphasis on historical priority of names led Ride (1991) to argue that justice for living zoologists rather than dead ones should be the priority. A poll of active systematists in the UK in 1991 revealed that the proportion of time spent on investigating nomenclatural issues rather than the scientific study of material ranged from 1 to 75%, with a mean value of 19.5%, i.e. about one day per week for a full-time researcher (Hawksworth 1992). Attention is now being focused on how the effectiveness of the nomenclatural systems can be improved, motivated by the need to: (a) minimize the time systematists have to spend on historical and legalistic work; and (b) restrict name changes for non-scientific reasons (Hawksworth 1991b). Significant changes to this end were made in the latest edition of the International Botanical Code (Greuter *et al.* 1993), and the first steps towards a harmonized and unified system of nomenclature for all groups of organisms have been taken (Hawksworth *et al.* 1994; Hawksworth 1995b with the

support of IUMS IUBS. An International Commission on Bionomenclature to advance this initiative is being established.

While biosystematists need to reconsider their working practices so as to optimize their effectiveness, this cannot be expected to make a significant overall contribution to the problem of the 'taxonomic impediment' to biodiversity investigation (Solbrig 1991). It is an inescapable conclusion that the currently employed workforce is seriously inadequate for this task. The issue of how to increase the human resource is considered further in Sections 7.4.3 and 13.

Conclusions

A wide variety of resources is required for the objective assessment of the extent of biodiversity and the realization of its potential both to benefit humankind and to contribute to the well-being of the planet.

The number of protected areas is substantial, but fewer than 5% have been thoroughly inventoried for even one major group of the biota. In consequence, the contribution of such sites to our understanding of biodiversity and ecological processes at the community level is not being realized. Marine stations are widely distributed and linked by a number of active regional networks.

Biological reference collections are the material basis for biodiversity assessments; they include anchors for the application of scientific names, and an immense wealth of information pertinent to inventory production and distributional studies. There are some 2.5 billion specimens in such collections, but accessing this information remains a major problem. Most such collections are inadequately equipped to cope with the demands of the resurgence of interest in biodiversity, with serious consequences for curation standards.

Living collections are a key resource for *ex situ* conservation and are necessary for assessments of biodiversity within and between species. The approximately 1600 botanic gardens hold over 4.5 million accessions representing about 80 000 plant species, but this is only some 30% of those now known. The 2000 or more zoos, insectaries and aquaria world-wide collectively maintain at least 5900 species.

Genetic resource collections are a key resource for the assessment of the utility of particular organisms and for breeding, as well as for maintaining the genetic variability of species. Plant germplasm collections amount to some 4.32 million accessions, but while representing some 6000 species in total, about 3 million of those accessions relate to only about 100 species. For fungi and other microbes, such collections are the only practical source of some species: 482 collections of fungi and other microorganisms collectively hold 786 328 strains, representing almost all isolated bacteria, about 17% of the known fungi, and much smaller proportions of algae, protozoa and viruses.

The major documentation on Earth's biodiversity is inaccessible to those with the greatest need for it. Potential users need means to identify and locate what exists and what they need. Electronic systems for the capture and dissemination of the required information exist, but many vital data are not yet available in such formats. Molecular sequence data are consolidated by only seven centres, data from which are largely accessible through the Internet. The lasting value of these data would be enhanced if vouchers were preserved.

The human resource required for biodiversity assessments includes professional systematists, 'amateurs', parataxonomists and indigenous peoples. Estimates of the number of biosystematists vary, but only about 7000 are actively involved in species descriptions. There is currently a mismatch between the number of known and estimated species in different groups and that of the specialists working on them. Bacteria, fungi, nematodes, certain groups of insects, and viruses are particularly poorly served. The building up and focus of the human taxonomic workforce will be critical to the implementation of national biodiversity programmes.

Major and concerted international action is necessary to improve the organization, deployment and replenishment of the systematic resource on a scale hitherto not envisaged.

EXECUTIVE SUMMARY

Section 9 provides decision-makers with guidelines for creating or enhancing the national capability to manage and disseminate biodiversity information. Increasingly, such national capacity is required for the best management of biodiversity, now recognized as a natural resource of potential economic value as well as one critical to maintaining the air, water, soil and other conditions essential to human life.

The first chapter (9.1) gives an overview of the nature of biodiversity information and the many ways in which such information is used. Beginning by drawing a distinction between information and data – information consists of data that have been organized, integrated and to some extent analysed – the chapter summarizes three categories of motivation for using biodiversity information. These categories are: public policy motivations (including compliance with laws, regulations or treaties), private sector motivations (including advancement of commercial interests such as biotechnology and natural resource development), and public interest and cultural motivations (including conservation and the advancement of basic science). To develop an effective biodiversity information management system, one must first understand the needs of all these potential users.

The authors emphasize that development of an information management system should not be contingent upon having any particular kind of technology. While high-tech, computer approaches have recently revolutionized this field, an effective system can be built using paper – including maps, card files, ledger books, field notes and bibliographies. The most critical step is to develop a good intellectual framework for the system, which can be modernized with high-tech approaches later if appropriate.

Moving on to specifics, the second chapter presents guidelines for deciding what kinds of information to collect. While the range of information types needed for biodiversity conservation is huge, limited resources mean that priorities must be set carefully from the start. To help decision-makers with that task, the chapter reviews all relevant data types and the many formats those data come in, then provides a list of criteria for identifying a user's own data requirements. Project managers should also find out what kinds of data have already been collected by others to avoid wasteful duplication.

Once it is known what kinds of data are needed, a system to manage them should be established before data collection begins. Chapter 9.2 provides guidelines for establishing such a system, focusing particularly on the documentation of procedures, resolving issues surrounding custodianship (who will be responsible for maintaining the data), and following (or setting) standards and guidelines so that the information will be useful to as wide an audience as possible.

Chapter 9.3 gives a comprehensive overview of the relevant tools and technologies in the field today. It includes a discussion of current trends in the availability of tools and the selection of appropriate tools, and reviews some of the tools developed in the field of biodiversity. The following categories are discussed in detail: data management tools, data analysis and modelling tools, and data dissemination tools.

Focusing specifically on dissemination, Chapter 4 emphasizes that, because every nation has its own unique biodiversity information needs, there can be no single recipe for success in data access and dissemination. Yet because of the vast (and growing) amount of information available – and the vast array of information types needed to solve any given biodiversity problem – a carefully thought out access and dissemination strategy is essential. To ensure successful transfer of information from one party to another, the use of data-exchange standards is important, and current standards for exchanging various data types are listed. Next, technologies that facilitate the presentation of biodiversity data are summarized. Finally, current methods of information dissemination are described – including paper, disks, CD-ROM and electronic media – comparing the uses, costs, advantages and disadvantages of these media.

Chapter 9.5 presents an overview of available information sources, describing different approaches to managing today's diversity of information, particularly special-interest computer networks and computer-based, or 'virtual', libraries. The chapter reviews the important efforts being made in the production of national, regional and global biodiversity assessments as well as the institutions that have focused on biodiversity information management. Finally, it reviews on-line sources of information on biodiversity as well as CD-ROM and diskette-based information products.

Stepping back from these details, Chapter 9.6 provides an overview of legal issues relating to biodiversity information management. Noting that international law has imposed obligations as well as restrictions on both public and private organizations regarding such information, this chapter begins by describing the various sources of current international law. These include international conventions that relate to biodiversity and international customary law.

The major legal issues that can arise in the field of information management include intellectual property rights, freedom of information, privacy, and liability. Chapter 9.6 examines the sources of law relating to each of these broad issues and gives examples of how they relate to biodiversity information.

Focusing on the development of institutional capacity, the final chapter (9.7) summarizes some of the most important issues to consider when establishing a national information management system. First, one should clearly identify the system's intended users and their specific needs. Another critical early step is to find out what kinds of information are actually available (or relatively easy to locate), identifying data-sharing options whenever possible.

An honest evaluation of current institutional capacity – including financial security, stability and ability to

collaborate with other institutions – is also important, as is an analysis of available human resources. The latter is often a problem in developing countries, which may lack trained professionals in the biological and information management fields, both of which are necessary for setting up a successful system. While often critical, training programmes must be carefully designed to develop the kinds of professionals that are most needed and to provide them with incentives to stay with the information management programme once they have been trained.

Finally, careful thought must be given to technology selection. As emphasized at the beginning of Section 9, sound information management principles are technology-independent. While computers have revolutionized the field in recent years, all the basic functions they perform can also be done manually. Before selecting a technology, decision-makers must consider the following: the problems they want the system to solve, the current and future costs of technology, ease of maintenance, flexibility, growth potential, and the human resources that will be required to run the system. If planners lock themselves into a particular technology before asking these questions, they are likely to end up with a system that matches neither their needs nor their capability to run it.

9.0 Introduction

Virtually every section of this Global Biodiversity Assessment makes a strong case for the collection of biological and other relevant information *before* decisions affecting biodiversity are made. Increasingly, the appropriate use of biodiversity information is also required by national and international law. The goal of Section 9 is to provide decision-makers with guidance for enhancing their nations' capacities to manage and disseminate biodiversity information. While enhanced greatly by the use of computers and other technologies, these activities can be carried out successfully with devices as simple as filing cabinets, card catalogues and paper maps.

Although information management and dissemination has long been viewed as an essential government activity, traditionally most effort has focused on social and economic issues. Natural resources routinely inventoried and monitored tend to be only those with direct economic significance, such as minerals, timber, land and soil, agricultural production and water resources. The development and use of other biodiversity information generally has not been a priority of governments and, with a few notable exceptions, most of the efforts in this area have been undertaken by the scientific research community or, to a lesser degree, by the non-governmental sector. Broadening the use of biodiversity information from these to other sectors of society is a principal challenge addressed in this Section.

Also encouraging an increase in the use of biodiversity information are the mandates of international agreements such as the Convention on Biological Diversity (CBD), the Convention on International Trade in Endangered Species (CITES), Chapter 15 of *Agenda 21*, the World Heritage Convention, and the Global Biodiversity Strategy, each of which calls for the effective organization, management and use of biodiversity information. The CBD in particular specifies a wide range of activities requiring the use of biodiversity and other scientific data. These activities include (but are not restricted to):

- biological survey and inventory
- monitoring and assessment
- education and training
- public awareness and participation
- restoration and rehabilitation
- ex situ conservation measures
- environmental impact assessment
- policy development
- assessment of economic benefits
- estimating conservation costs
- socioeconomic surveys and studies

The convention also anticipates extensive information collection and management through the so-called Country Study process. Already under way, or even completed in some countries, the studies' goal is to gather and analyse the biological, economic and social data needed to prepare the national strategies and plans the CBD requires. Beyond producing these products, the studies are intended to be the first step in an ongoing and evolving process. In essence, the convention and other recent international agreements are requiring the world's nations to develop environmental information infrastructures similar to those they have developed for military and economic planning.

Based on principles developed under the CBD, biological and genetic resources are also increasingly viewed as natural resources with potential economic value. In addition, such resources play a key role in providing so-called ecosystem services – maintaining the air, water, soil, climate and other environmental conditions essential to human survival (see Section 6). For all of these reasons, countries today have strong incentives to inventory and monitor the status of their biodiversity resources and to use this information for the intelligent conservation, management and use of those resources.

9.1 Biodiversity information: its nature and its users

9.1.0 Introduction

Previous sections of the GBA have described various tools available for collecting biodiversity and other environmental data. This section will take up where those left off – describing the tools that are available to *manage* data that have already been collected, *apply* these data, and *communicate* them to decision-makers and others who will use them to better conserve and manage biodiversity. The section also describes the types of *information sources* that will complement these activities, and identifies a range of examples.

Readers of this section will tend to be either those who generate information on biological diversity and/or have responsibility for managing it or those who are users of biodiversity information or could potentially benefit from the use of such information. Obviously, these two groups are not mutually exclusive, and there is considerable overlap between them. However, differentiating between information generators and users helps to frame much of the following overview, which briefly describes the nature of information (9.1.1), motivations for biodiversity information use and the diverse user constituencies (9.1.2), and criteria for success in biodiversity information management (9.1.3).

9.1.1 The nature of information

Clarifying the relationship between data and information – terms that are too often used interchangeably – is important

Figure 9.1-1: The nature of information.

for understanding the nature of information and its management, communication and use. A continuum describing this relationship links in a hierarchical fashion data, information and knowledge (Figure 9.1-1).

Data generally refers to the observations or measurements describing a particular entity or process. *Information*, however, usually refers to data that have been organized, integrated and to some extent analysed. *Knowledge* can be derived from information through further analysis, interpretation, and understanding. The ideal end product of this continuum is *wisdom* – in this case in biodiversity management – which is achieved through the intelligent use of knowledge. As one moves up the continuum from the real-world process of data collection toward wisdom, the primary stakeholders involved in each activity change – from those with a primarily local focus to decision-makers and others who are interested in the broad application of knowledge.

9.1.2 Biodiversity information use

In any effort to develop or improve biodiversity information management strategies, it is essential to consider who are the projected users of the information, what are their needs, and what is their level of technological sophistication. Only with a thorough understanding of these factors can system capacities and requirements be evaluated successfully.

Use of biodiversity information generally depends upon specific motivations. The different types of motivations therefore provide a perspective from which to view potential user audiences. Three principle categories of motivations – public policy motivations, private sector motivations, and public interest and cultural motivations – are described below.

9.1.2.1 Public policy motivations

These motivations for using biodiversity information primarily involve compliance with laws, rules, regulations or treaties. They derive from all levels of human activities,

from village-established rules, through state- or national-level laws and policies to international treaties.

As emphasized in the introduction to this Section, legal incentives are some of the most powerful drivers of biodiversity information management today. It is no coincidence that those countries that have strong environmental legislation – be they industrialized or developing countries – also have the most heavily used biodiversity information management efforts. The rigour with which these policies or regulations are enforced, however, has a large influence on the degree to which they provide motivation for biodiversity information use. Lax or non-existent enforcement leads to low compliance, and therefore little incentive to apply this information. The enforcement mechanism behind many public policies is economic in nature. At the level of individuals or companies, this generally translates into fines or delay costs, whereas for governments this may translate into trade barriers or reduction in foreign assistance financing.

9.1.2.2 Private sector motivations

These motivations relate to the need for biodiversity information to advance commercial interests. Companies involved in plant breeding, ecotourism, biotechnology or natural resource management may have a vested economic interest in receiving and applying such information. A corollary, however, is that biodiversity information developed by private interests may be treated in a more proprietary way than information developed for other reasons. The need for information to avoid costly penalties or regulatory delays spans both public policy and private sector motivations. In addition, the private sector is increasingly seeking biodiversity information to avoid potential environmental problems or to develop contingency plans.

9.1.2.3 Public interest and cultural motivations

Public interest motivations for the use of biodiversity information are growing rapidly. They include efforts by both government and non-governmental institutions, as well as individuals, to apply biodiversity information in ways that advance the conservation and sustainable development of natural resources. Much of the work in biodiversity information management to date has been undertaken with public interest incentives as a primary motivator. This often takes the form of encouraging proactive efforts for environmental protection, such as the establishment and management of protected areas. Access to environmental information has also proved to be a powerful force for empowering local people to take an interest in and feel responsible for their biodiversity resources.

Cultural motivations – including scholarly pursuits and the incentives traditional societies have to document knowledge

about local plant and animal species – are responsible for the vast amount of biodiversity information that has been acquired over the past few hundred years. Most of the widely known basic information about species and ecosystems has come from scientists and interested amateurs driven by intellectual curiosity. In addition to being the major source for exploration and information generation, these academic and scholarly endeavours also constitute a major incentive for the use of existing information. Indeed, the advancement of scientific inquiry builds upon a foundation of existing knowledge, providing the basis for the strongest historical use of biological diversity information.

9.1.3 Information flow

Often, those most in need of biodiversity information either fail to get the information at all, or find themselves overwhelmed with information that they cannot assimilate (WRI *et al.* 1992). This is a failure of the effective flow of information caused by one of the following factors:

- Poor access to existing information, including:
 - cost of access
 - unpublished material
 - restricted access (for whatever reasons – political or personal)
 - inadequate information on what is available
 - multiple sources
 - lack of integration
- Information does not meet user requirements, including:
 - wrong format
 - inadequate documentation
 - poor (or undocumented) quality
 - not scientifically credible

Figure 9.1-2 presents a representation of information flow taken from WRI *et al.* 1992.

This section therefore not only deals with the actions required to improve the management of biodiversity information, but also those actions required to improve the flow of that information.

9.1.4 Criteria for success in information management

9.1.4.1 Internal criteria

Internal criteria for success are primarily those factors related to the effective and efficient functioning of the institutions responsible for information management. Key to achieving this goal is: (1) having a clearly stated *mission* and *objectives* against which activities and progress can be measured; (2) having appropriately *qualified staff* able to

implement the objectives; and (3) having enough *stability* in governance and finance to allow proper long-term development.

For many information-orientated institutions, there is a dynamic tension between the need to produce short-term products and the desire to accumulate information over the long term. For financial reasons, and to provide needed services, many information management efforts follow a very project-driven pathway. This ‘consultant model’ often involves intense work and detailed information development about a specific topic over a short time span. Contrasting with this is the more strategic goal of long-term accumulation of information that will be capable of informing a broad range of users rather than just a project sponsor. This often involves long-term data development and analysis that identifies and addresses broad societal needs.

While following only the first model will tend to produce information that is quickly lost or forgotten, following only the second may lead to the perception of irrelevancy in the short term. Thus another internal criterion for success is the balance struck between these two approaches, which are not in fact mutually exclusive. Short-term project work can and should feed into a long-term strategy for accumulating knowledge, and long-term information collection and management efforts must provide short- and mid-term benefits in order to justify their existence.

One way to strike this critical balance is to develop a phased approach. Early phases can focus on meeting important short-term goals, while simultaneously keeping an eye on future goals. Such an approach also allows a new institution to start out using a lower level of information management technology – making use of the staff, budget and tools immediately available – switching to more advanced approaches when the organization is ready. Key to the success of this approach is designing projects so that changes in tools are possible, i.e. not becoming so wedded to one technology that changing to another is impossible in the future.

Although high-technology approaches to information management have revolutionized the field in recent years, an unwanted side effect may be that those who do not have these tools are discouraged from entering the field. Well-organized data on paper – in the form of maps, card files, ledger books, bibliographies and field notes – are an essential part of information management. Preparing the intellectual framework in which the original data will be collected and organized is far more important than employing the most modern tools. By concentrating initially on this phase, thereby minimizing the technological barrier, more institutions will be encouraged to develop biodiversity data management capabilities in the first place. Well-organized data can be easily transferred to electronic systems at a later date.

Figure 9.1-2: The information flow (from WRI/IUCN/UNEP 1992).

New institutions should also not be discouraged by gaps in the information available to them. If developing according to the phased approach described above, these institutions can use estimates to fill these gaps during their early stages of development in order to meet short-term goals. As they become available, actual data can replace estimates in later stages.

9.1.4.2 External criteria

Perhaps the most important criterion for evaluating the success of biodiversity information management activities is the degree to which the resulting information is useful to, and used by, their target audiences. Ideally, this usefulness should translate into influencing and improving key government as well as societal actions. Such actions range from preparing state-of-the-environment reports and improving the environmental sensitivity of development planning to enhancing the ability to restore damaged ecosystems and increasing the effectiveness of conservation action in general.

Measuring the impact of information on such actions, however, is subjective at best. More quantitative measures include the number of biodiversity information users, the sectoral breadth of users, and the number of requests for information. Regarding the latter, it is important to distinguish between requests that come from the biodiversity information management community itself and requests from users, particularly decision-makers, in other sectors.

Critical to meeting this criterion for success is ensuring that the availability of information is known to those who need it and that they find the information both relevant and readily accessible. The definition of ready accessibility will differ from country to country and among user groups, depending upon the level of technological sophistication. Optimal accessibility in one context may be responding to telephone, mail or personal inquiries, whereas in others nothing less than on-line computer access with full multi-media capabilities will be considered truly accessible. In either case, feedback

mechanisms are needed so that information managers can keep track of changes in user needs as well as the relevance of the information provided.

9.2 Data collection and management

9.2.0 Introduction

For reasons discussed earlier, it is necessary to draw together a wide range of information on which conservation priorities and actions can be based (9.2.1). Data gathering can be an endless process, however, unless clear boundaries are specified and linked to unambiguous objectives.

A common error in conservation planning is to allow researchers and data managers to set the parameters for data acquisition independent of the interests of information users. Thus an information management strategy should always be made a part of any conservation planning process (see 9.2.4). As part of this strategy, the information needs of users must be determined through a continuing dialogue that identifies and sets priorities for types of data required as well as the processing and models needed to make it useful (see 9.2.2). Information users should in fact participate in *all* phases of the development and maintenance of an information strategy.

With limited resources available, setting data collection priorities is critical. Priorities will vary according to specific needs and requirements, but decisions on the depth and breadth of data gathering, particularly if additional research is envisaged, must be subject to a thorough assessment of the costs and benefits involved. Particularly pertinent is the need to identify those data sets with multiple applications and those that are irreplaceable (perhaps because of environmental change).

It is also essential to consider what work has already been done. Many people have collected data for many purposes for many years. Before developing any new data collection and management operation, it is essential to review what information already exists, who is collecting it and how, and who is managing it and how. There is no sense in expending time and resources on repeating existing information collection and management operations.

In the past there has been a tendency to assume that it is best to collect and manage all information in one central location to ensure its adequate integration and application. However, this may not always be true and may in fact result in information not being used by those who need it most. What is important is not centralized information collection and management, but ensuring that the information is available, compatible and comparable. This is facilitated by the application of appropriate standards to the process (9.2.6); custodianship by the appropriately qualified centres of excellence (9.2.5); good

communication between information collectors, managers and users; and careful co-ordination of any information collection and management effort (9.7).

9.2.1 Types of data

Effective biodiversity management is ultimately concerned with influencing the interface between human and biological systems at local, national and international levels. International trade in natural resources is potentially as significant a factor in biodiversity conservation as are national forest policies or local community action. Similarly, the market value of a particular resource may be as important a factor in its conservation as the resources applied to its conservation.

Thus the range of data types needed for biodiversity conservation and management varies considerably (see Figure 9.2-1). The following paragraphs identify some of the most important information types necessary. Although brief, these paragraphs begin to demonstrate the extent of interrelationships among information types needed to study and manage biodiversity effectively. It is essential that such interrelationships are kept clearly in mind when planning both data collection and data management strategies.

Another important consideration is the dynamic nature of most biodiversity and economic data. The status and distribution of species and habitats are constantly changing, as are the costs of their conservation and the economic benefits of their use. When developing data collection and management systems, it is critical to design databases that allow for regular, systematic updating as well as gathering a diversity of new data.

It is also essential to be aware not only of the ‘scientific’ and ‘economic’ data of modern societies, but also of traditional knowledge. The recording of this knowledge may require particularly careful thought because of the nature of the information and the sensitivities involved in its collection.

9.2.1.1 Natural environment

Biological information and the many forms that information takes is a primary focus of the entire Global Biodiversity Assessment. Earlier sections discuss information requirements for species, ecosystem and genetic resources, covering issues ranging from status and distribution of resources to functional relationships (including ecosystem processes) and the development of tools to support the science.

Information on physical factors such as climate, topography, hydrology and substrate allows one to place biological data within a physical context and facilitates the development of predictive models (as the distribution of many species and vegetation types can be predicted by a combination of physical characteristics). Physical factors also have a significant impact on ecosystem processes (the

Figure 9.2-1: Different types of data related to biodiversity.

interaction between the biological and physical), potential use of biological resources, and management strategies for those resources. Such information is essential in order to assess and manage biodiversity effectively.

9.2.1.2 Society

Use and abuse of biological resources is essentially a function of social and economic factors. Important data within this category include human population structure and trends, the distribution of that population, and the ways in which distribution changes over time (both short term and long term). More difficult to measure but also relevant to resource use are factors such as quality of life (including literacy, relative income and life expectancy) and aesthetic values.

9.2.1.3 Relation between natural environment and society

The management of biodiversity is a function of this interaction, and it is vital to get an accurate picture of how human activities affect the natural environment. Most obviously this includes data on land use and pressure on natural resources, including forestry and fisheries practices, farming methods, location of transportation routes, and the use local people make of natural resources. Such information must include not only a review of the status and distribution of the various

types of activity, but also of the technologies involved. Do forestry practices, for example, involve cutting selected trees with saws or clear-felling large areas with heavy machinery?

Assessing the value of local economies is also essential. To ensure effective and efficient biodiversity management, one must know the true value of biodiversity as well as the costs and benefits of different management options – including the costs of managing protected area systems, the level of income derived from tourism associated with natural resources, and the value of indirect benefits such as watershed protection. Some of these values require assessment of biodiversity's true value, methodologies for which are only now being developed (see Section 12).

Identifying and monitoring pressures on environmental resources and threats to biodiversity is essential (see Section 7). To do this effectively, data collection programmes must go beyond the obvious, direct threats to biodiversity and also identify and record the underlying causes of those threats – such as overpopulation, poverty, and government policies, linking these data as necessary with other types of data.

Biodiversity conservation requires effective resource management. To assess the effectiveness of that

management, information is needed not only on the status and distribution of biodiversity, but also on current and past resource management activities. This would include information on protected area management, coastal zone management and species management strategies.

9.2.1.4 Auxiliary information

Good biodiversity management not only requires easy accessibility to sources of all kinds of information listed above but also appropriate contacts for procuring that information. This may include bibliographic information on who has published what and where, basic information on names and addresses of qualified experts, sources of information on reliable and appropriate models, metadatabases (see 9.4), information on projects that have been conducted, and so on.

9.2.2 Identifying data requirements

Data collection and management should be done in a systematic and planned manner, identifying *first* the problems that must be solved before deciding what data are needed to solve them. Although collecting and managing data are only part of any project life-cycle, they often, by accident or design, become the primary focus of the project. While understandable, given the ease with which data can be recorded and analysed by computers, this ‘data first’ approach can increase the risk of misusing resources, as well as developing research activities that do not address priorities.

The range of relevant information is so huge that project managers must distinguish from the start between information that is necessary, information that is desirable, and information that one can do without. These decisions depend on:

- a clear definition of the problems to be solved and the needs of those who will solve them;
- an assessment of data requirements (including type of information, level of detail and periodicity of update);
- an assessment of available resources (including financial and human resources and necessary equipment);
- the extent to which information is already available in a useful form; and
- ongoing information management activities that can be used or adapted.

If data collection and management are planned within the confines of a specific project, the activities involved will be bounded by the project’s required outputs and products. For instance, a project aiming to evaluate the land cover characteristics of a region may employ the expensive

option of detailed sample surveys over the relatively cheaper, yet coarser, option of classifying satellite imagery. This would be an appropriate decision if the project required a product that was detailed and repeatable.

If, on the other hand, the objective is to develop a national biodiversity database, the task is somewhat more difficult, because resources will never satisfy the wide range of needs. With limited resources available, setting priorities for the types of data to collect is critical. These priorities will vary according to planning needs and requirements, and identification of who will use the information and how. Although decisions on the depth and breadth of the data gathering will be subject to an assessment of costs and benefits, general priorities for types of data to be collected include the following (adapted from UNEP 1993):

- data that can be used for more than one purpose;
- data that provide a baseline for monitoring conservation action;
- data that are important for decision-making;
- data on the social and economic values of biodiversity and protected areas;
- data supporting policy and conservation programmes;
- data on genetic resources, including medicinal plants and wild ancestors of domesticated species;
- data on species that could serve as indicators of ecosystem health;
- data on ‘keystone’ and ‘flagship’ species and habitats;
- data on alien or exotic species, potential threats to indigenous biodiversity;
- data on biodiversity known to be threatened;
- data on biodiversity protected within conservation areas;
- data on threats to biodiversity;
- data on potential rates of biodiversity loss;
- data on species and habitat distribution;
- data on biodiversity function and ecosystem services provided;
- data on landscape infrastructure and pattern;
- data on species and sites of special significance outside protected areas; and
- data on the status/distribution of protected areas and their biodiversity.

It should be noted that as well as being required in their own right, data may also have a value in supporting other data, or in acting as a surrogate for data that either cannot be collected, or would be too costly to collect.

9.2.3 Data formats

Not only must project planners decide what data should be collected, but they also must decide how those data should be managed. While much of this is discussed in Chapter 9.3, a critical early aspect of data management is the format of the data collected. The following paragraphs give an introduction to this topic, although they are neither all-inclusive nor mutually exclusive.

9.2.3.1 Numeric data

There are two main types of numeric data: primary data and derived data. Primary numeric data are obtained directly from many types of survey ranging from counts of species in particular locations to measurements of rainfall, tree growth or the length of a bird's primary feathers (which might be used in identification and taxonomic work). A count results in a whole number, while a measurement is made on a continuous scale. Primary numeric data can also be generated automatically from recording machines. Note that in all cases it is important to differentiate between zero and no value – zero may be the actual value.

Derived numeric data are obtained from the manipulation and analysis of other numeric data sets. The altitudinal range of a protected area, for example, can be derived from subtracting the lower altitude from the upper. Another form of derived numeric data is ranking. For example: Everyman's National Park in Batavia is the third largest in the country (based on a ranking of sites by size) and the second most important for conservation of endemic species (based on analysis of species records).

Numeric data are used extensively in modelling and in the derivation of categoric data (see below). For instance, information on temperature, rainfall and altitude at a particular site (all numeric data) can be used to predict which Holdridge 'life zone' (see Section 2.3.3.3) it lies within. And because numeric data are by definition structured, it is possible to structure their management quite carefully, including checking data entry to ensure that figures input are theoretically possible.

9.2.3.2 Categoric data

Categoric data are classified or coded non-numeric data, which could include records of variables such as soil type, land cover, forest type, species and protected area designation. These data are structured, usually through a thesaurus or data dictionary, and can be checked for allowed values. As mentioned above, categoric data can be derived from numeric data. For example, classification of

remotely sensed data often results from the derivation of categories from numeric data. Qualified with numeric data, categoric data are often used in association with maps.

For very sound reasons, primary data should take precedence over classified categoric data wherever practicable. This will ensure that if the categories become obsolete, or one wishes to use another classification system, new categories can be readily identified from the primary data. If the primary data are not available, then expensive data re-collection exercises will become necessary.

9.2.3.3 Text

Text consists principally of descriptions – including descriptions of protected areas, species and threats. By its nature, text is much less structured than other kinds of data and can become subjective unless careful controls are placed on its compilation through, for example, definition of paragraph headings, specification of paragraph contents, and vocabulary control. Text, when attached to a database or map, can provide valuable extra description. It can be used, for example, to check more thoroughly the identity of a species once a database has been used to identify it. With recent developments in text manipulation using computers, such as the use of 'hypertext' links (9.3.2.3), the value of text description has increased considerably.

9.2.3.4 Spatial data

Maps have always been a valuable tool for the storage and presentation of information, because they provide a ready identification of the nature of the landscape and the relationship between various features within it. Basically, any feature that can be 'geo-referenced' (its location identified with respect to other geographic features) can be placed on a map. Such features range from known locations of particular species to the extent of remaining threatened habitats, mean daily temperature at various meteorological stations, and the location of major population centres. Maps are a good tool with which to synthesize and present complex information in a format easily understood by a broad spectrum of people, and the development of computer tools for handling spatial data (9.3.2.2) has increased the potential for map generation, manipulation, and analysis.

9.2.3.5 Remote sensing data

There are several forms of remote sensing, based on the kind of sensor used (radar, visible and infrared, thermal) and on the kind of platforms from which the sensor operates (satellite, aircraft). Remotely sensed data generally require careful interpretation and validation, without which the data may be misunderstood or even misused. Their advantages include their potential to cover very large geographic areas, and their repeatability, providing an opportunity to monitor change. Their disadvantages include

the difficulty of interpreting these data, their cost, and the fact that they can result in very large amounts of information, meaning that storage and analysis can also be costly. It is therefore essential that the implications of using remotely sensed data are carefully assessed before launching such a project.

9.2.3.6 Images

A variety of useful data come in the form of images. Photographs and drawings of individual species and parts of their bodies, for example, are an essential aid to identification. Photographs of a particular landscape feature taken periodically over time are a valuable resource for assessing change. Combining images and sound, video adds a dynamic factor that allows, for example, the recording of movement patterns and animals in particular habitats. Video may be particularly pertinent to the recording of traditional knowledge.

9.2.3.7 Sounds

Sound may not be an obvious data type, but it has significant value in identifying certain species. In fact, experts can use sound to confirm the presence of some species, particularly birds, without actually seeing them, which can be particularly valuable in dense vegetation.

9.2.4 Data collection and management strategies

Having identified the information required, the next step is to review what data already exist and what data collection and management programmes are already under way. Without this review, time and resources may be wasted and other institutions or individuals antagonized. Methods should always be developed to make the most efficient use of existing data, whatever their quality. However, in order for data to be reliable, they must also be validated or accompanied by information that indicates the level of reliability.

Following this review, the actual data sets required can be defined. Data sets are groups of related data and attributes about those data and their collection. Such data sets are usually sectoral in nature and are linked to other data sets through common fields. For example, geographical location can be used to link data sets on protected areas with data sets on species distributions.

Because most project resources are finite, good science and good decision-making require the application of appropriate data collection and management strategies. Given the aesthetic appeal of GIS, image processing systems and other ‘high-tech’ approaches (9.3.2.2), project managers may be tempted to believe that low-quality data have been enriched simply through its presentation, advocating ‘garbage in, gospel out’. There is also a tendency to go for high-tech solutions when low-tech solutions are perfectly adequate. Good strategic planning can avoid both problems.

9.2.4.1 Data collection strategies

Having identified the types of data required and the relevant data collection and management programmes already available, project managers must devise strategies for both compiling and transforming existing data and collecting new data. Such strategies will involve many organizations, and those developing them must recognize – in advance – all potential constraints, including the adequacy of existing data and availability of resources. In particular, the following issues need to be carefully considered:

- negotiations with holders of existing data and managers of existing programmes;
- availability and costs of appropriately skilled labour;
- capacity to provide supporting materials;
- time constraints;
- logistics of handling field results;
- adherence to collection standards;
- quality controls and validation methods;
- integration;
- level of detail required including needs for estimates or approximations;
- collection methods;
- need for systematic time series, change analysis, update; and
- appropriate incorporation of traditional knowledge.

It is also important at this stage to develop strategies for communicating to those collecting data why it is valuable for them to do so, and where necessary developing appropriate training programmes. Commitment to the process at all levels is essential to success.

9.2.4.2 Data management strategies

Project managers must also devise strategies for managing their data. Because data collectors must be aware of any specific requirements (relating, for instance, to data type, quality assurance, digital media formats, communications, and time scales), planning such strategies should take place before the data are collected. It is at this stage that very careful thought must be given to the appropriateness of technological solutions to data management tasks.

Issues that should be considered in developing the strategy include:

- negotiations over coordination and custodianship with managers of existing data management programmes (9.2.5)

- evaluation of appropriate tools (9.3 and 9.7.3)
- identification of investment required (9.7.5)
- identification and adoption of standards (9.2.6)
- personnel/institutional issues (9.2.5 and 9.7.4)
- location of data management programmes
- documentation and metadata (9.2.4.3 and 9.2.4.4)

9.2.4.3 Documentation

It is essential that data collection and management procedures are well documented to facilitate not only the application and dissemination of data, but also to ensure continuity of data collection procedures. Documentation should cover data collection and management procedures as well as issues of data quality. For example, each data set should have information on:

- source of data
- data lineage (actions performed on data since collection/derivation)
- accuracy and precision
- date and life expectancy of the data
- data field definitions
- collection methodology
- comprehensiveness
- consistency
- constraints on use

Data that are fit for one purpose may or may not be fit for another. Only with adequate documentation on data sets can this be assessed, and appropriate caveats added to applications of these data.

9.2.4.4 Metadata

With the rapid increase in information available and the need to use information, metadata – information about information – is becoming increasingly important. Documenting what data sets are found where, what they contain, and how they are put together forms the basis for the development of data directories (see below), either published or electronic. The development of both documentation and metadata should be considered an essential part of good information management practice.

Typically, a metadatabase might include two types of information:

1. About institutions that hold relevant information:

- basic details (who, where, and function)

- available resources (human, technical, financial)
- key linkages (who currently works with who, and how)

2. About relevant data sets:

- description of data sets (what, purpose, format, and how managed)
- coverage (geographic, thematic, time scale, completeness, limitations and gaps)
- access (availability, cost, formats available, and documentation)

9.2.5 Custodianship

All data sets required in environmental information systems are complex, thus their establishment and maintenance requires the knowledge of specialists. This specialist knowledge is needed not only to acquire and maintain data, but also to document the data and advise clients on its fitness for various potential uses. Custodianship is the means by which responsibility for data sets (or defined parts of data sets) is assigned to and accepted by the most appropriate organizations. It provides a mechanism to ensure that each data set is established, maintained and made available by the organization best able to do so.

Custodianship includes responsibilities in data acquisition, management and documentation as well as rights to determine the conditions under which data are accessed and used. Custodianship may also include responsibility for modelling and analytical tools, including expert systems and decision support systems (Busby and Walton 1994). A custodian should consult with all categories of potential users of a data set to ensure that, as far as practicable, their requirements are taken into account. Where user requirements exceed those of the custodial agency for its own corporate objectives, additional resources may be required.

9.2.5.1 Criteria for assigning custodianship

The most appropriate custodian for a data set is likely to be the agency that meets one or more of the following criteria:

- has sole statutory responsibility for capture and maintenance of a data set;
- normally is the first to record changes to a data item;
- is the most competent to capture and/or maintain those data items;

- has the confidence of users that it will continue to meet its commitments to data collection and maintenance; and
- requires the highest integrity of a data item.

Certain data sets are of very high national priority, and it is particularly important to identify appropriate custodians for these. The data sets that are required to support national objectives or those of a number of agencies would be among the first to be considered. Every country, for instance, needs an accurate and stable data set representing its national boundary, which must be maintained at a resolution and accuracy required by key national agencies and their programmes. One agency, in this instance normally some central mapping agency, should be assigned as custodian for this data set. If a country cannot do this, consortia of countries could share custodianship of these data in a regional centre.

9.2.5.2 *Responsibilities of custodianship*

A custodian should provide the following services:

- organize the building of the data set
- update the data set
- ensure the continued integrity of the data, e.g. through making periodic copies of the data
- archive the data set, whether as hard copy or electronic copy
- ensure appropriate access to the data set
- maintain documentation of the data set
- advise on appropriate uses of the data set

9.2.5.3 *Custodianship in networks*

The principle of data custodianship in information networks is that all data available to the network is ‘corporately owned’, meaning that many network users have a stake in those data. Designated custodians, however, have responsibilities to collect and maintain the data and also rights to regulate their access and use. Conditions may be attached to data on a network: for example, data may be used for government decision-making, public information or research purposes, but not for any commercial purposes without a specific licence to do so.

Custodians are responsible for licensing arrangements, which often become complex. For example, some agencies in a network may own licences to use data that would be infringed if those data were passed through the network, but not if they were passed directly to certain other networked agencies. In other cases, certain agencies may be authorized to access data in raw form, while others may only be able to access more generalized versions.

9.2.5.4 *Difficult issues in custodianship*

Identified high priority data sets that underpin the corporate objectives of well-established agencies tend, on the whole, to be well maintained and documented. Difficulties can arise where an agency has built a data set of relatively low priority to that agency but of high priority to another, which itself is not in a position to be the custodian. An example might be a digital elevation model, which would be required by a number of resource management agencies, none of them with the expertise to construct and maintain such a product. In such cases, some higher-level framework agreement should be negotiated between the various stakeholders and any resource implications resolved.

Another problem can arise when a number of agencies – such as research groups – collect data on, for example, the distributions of animal or plant species. Each data set may be accumulated for different purposes, meaning that the various data fields, even when congruent, may be collected to different standards. It can be extremely difficult to integrate all these disparate data sets in order to build a nationally coherent data set. Even if such a data set is feasible, who is then the custodian of the data – the agency that integrated them or all the individual contributors? If the latter, how does one resolve the fact that each small research group may have no interest in long-term maintenance of the data? In fact the group may even disband after the project has been completed.

9.2.6 *Standards and guidelines*

One means of ensuring the wide applicability and relevance of information is the development and promotion of standard methods and classifications to facilitate information exchange. While it is difficult to find international consensus on many aspects of data collection and management it is still possible to develop basic principles that ensure the continuity of data and their analysis among researchers. Encouraging the application of such standards is very important, yet wide application comes not from adopting and promoting all that is new and sophisticated, but from fostering a strategic vision of future compatibility. It is far more important that some standards are used – and that they facilitate access to information – than it is for the newest standards to be adopted.

The issue of defining and adopting a set of standards is problematical because, ultimately, all standards are compromised by available resources. It is, for instance, expensive to guarantee well-documented and quality-controlled data. In situations where resources are scarce, it is unreasonable to expect methodologies and analyses that demand a high degree of investment and sophistication. It would, for example, be inappropriate to suggest that wildlife protection should adopt a standard requiring data-

intensive methods in a country that is not easily surveyed and has limited resources.

In developing and promoting standards, one must also be aware of the potential for over-standardization, which constrains new initiatives in the development of what is still a very new science. For instance, there are new possibilities for measuring plant and animal distributions using the Global Positioning System, which have changed current requirements for standardizing qualitative/quantitative procedures for citing field observations.

These issues should encourage institutions interested in developing standards to consider promoting 'guidelines' and methods of 'harmonizing' data (making different approaches comparable) in cases where universal standards are premature. The development of such standards and guidelines is the focus of work currently under way under the auspices of UNEP and a range of other organizations, which should facilitate the collection, management and application of data.

9.2.6.1 *Potential areas for the development of standards*

The following list provides an overview of areas where standards might be developed or adopted and more widely promoted. Such standards may be developed at the national or local level for specific projects, but the more widely standards are adopted, the more useful and comparable the data become.

- data collection methods and survey protocols
- documentation and quality assurance
- key products – particularly those that may be specifically defined by international agreements such as the Convention on Biological Diversity
- cartographic projection
- spatial data accuracy
- baseline classifications (such as species, protected areas)

9.2.6.2 *Potential areas for the development of guidelines*

The following list provides an overview of areas where guidelines might be developed or adopted and more widely promoted. As with standards, such guidelines may be developed at the national or local level, but the wider their applicability the better.

- information collection methods
- information management methods
- development of reporting and products
- data application (modelling)
- data validation

- user interface
- vegetation classification
- harmonization of data

9.3 Tools and technologies

9.3.0 *Introduction*

While it is possible to collect substantial amounts of data relatively easily, these data alone do not provide the understanding of biodiversity that is so critically needed today. For that understanding, it is necessary to have the tools to make the data useful to decision-makers and others. This chapter will review the most important tools and technologies now available to manage data and convert them into valuable information.

Different tools are needed by each of the many kinds of players in today's field of biodiversity management. These players include: the so called 'experts' working in a very specific field (for example, database experts, GIS experts, computer experts and biodiversity experts), planners who use input from experts to transform data into information and provide it to decision-makers, and decision-makers who take this information and use it to make policies and initiate projects.

The tools discussed in this chapter include those that are needed to manage, analyse, model and disseminate biodiversity data (see Figure 9.3-1). They are all computer tools, because the authors have assumed that there already exists wide familiarity with non-computer tools such as card indexes, filing cabinets, annotated maps and libraries. The issue of establishing libraries and similar information services is discussed by, for example, Webb (1988).

9.3.1 *Data management tools*

One challenge when selecting a data management tool is that of ensuring that data can be retrieved in whatever form users require. A wide variety of such tools are now available, ranging from written text on paper, filing systems and libraries to sophisticated computer databases, including geographic information systems. Assuming a general knowledge of non-computer tools, this section concentrates on computer tools for information storage and management.

9.3.1.1 *Database management*

Until the mid-1970s 'database management systems' (DBMS) for organizing data were commonly based either on a hierarchical structure or on a network structure. These approaches limited their application in the environmental field because they were unable to handle either the complexities usually encountered in environmental data or the complex relationships among these data.

In recent years, the development of 'relational database management systems' (RDBMS) has had a significant

Figure 9.3-1: The information process.

impact on data management. RDBMS organize information as a set of tables or files, with relationships between files determined by common values in the ‘related’ tables. Thus the RDBMS model for organizing data offers a flexible database structure that is easy to define, expand and change. Accessing one type of data allows one to explore relationships with others that are needed for effective environmental information analysis.

Associated with RDBMS has been the creation of ‘Structured Query Language’ (SQL). This is an English-like retrieval language for querying relational databases. It borrows mathematical set theory concepts for expressing the query. More important, SQL is database-independent, allowing its use with many available RDBMS systems. The standardization introduced by SQL frees organizations from being committed to any particular brand of RDBMS and introduces even greater flexibility.

SQL also has benefitted from the development of client-server database architectures. Normally a PC database is a single program that handles both the data files and the user interface (forms, reports and so on), but these responsibilities are split in a client-server system resident in different computers connected through a network. One application – the client – looks after the user interface, while another – the server – manages the data files at a central location (usually the network file server), and can deal with many clients on a network simultaneously. This architecture is currently incorporated in most commercial RDBMS packages, and facilitates the development of data sets that can be accessed by a wider range of users in remote locations.

The ‘Object-Oriented Database Management System’ (OO-DBMS) is a relatively new approach that could further improve one’s ability to manage groups of data items (objects) and make connections between objects. The OO-DBMS approach provides an intuitive and powerful way of creating and implementing data models of complex systems such as ecosystems. Because this technology is still immature it suffers from the poor performance and lack of standards that RDBMS suffered from a decade ago. In the future, however, this technology will allow information compatibility on a much broader scale than is possible today.

There have also been recent developments in distributed database systems (DDBMS) – single logical databases physically distributed on several computers that communicate through a network. These provide multiple access to databases as well as mechanisms to avoid conflict in update, retrieval and backup of data. DDBMS are particularly useful for very large databases where most users are concerned with only a small subset of the data. They also permit access to users with broader needs.

Currently, however, it is difficult to link existing databases in a DDBMS because of differing technology at each site. A possible solution to this problem now being developed is the ‘Federated’ database management system, which has the advantages of the DDBMS but also allows data communication among DBMSs of different data models, brand-names and access methods. (At the same time, each local DBMS remains autonomous.) The environmental policy decision support system of the future will no doubt

use this technology to link heterogeneous information collections in various countries and agencies. The technology is expected to mature in the next five to ten years.

As database management tools become more powerful and easier to use, many institutions responsible for biodiversity collections have developed specialized databases for the management of biodiversity collections or the analysis of regional or world data sets. Box 9.3-1 presents a selection of some of these tools.

9.3.1.2 Geographic information systems

Much biodiversity information is spatially orientated – it can be mapped. For many purposes, simple geographic information such as latitude/longitude, and links with geographic features such as countries or provinces, is quite adequate and can be used to produce simple map-based products. These need not necessarily be computer-based.

Computer map-based geographic information systems (GIS) have been used to manage environmental information and aid decision-makers since the inception of the Canadian Geographic Information System (CGIS, Canada Lands System Division, Environment Canada) in the mid-1960s. The basic advantage of a GIS is its ability to manage and perform complex processing on both spatial and statistical data and to permit the manipulation of geographic boundaries. This allows for the integration and summarization of environmental information using natural units – such as watersheds, natural forest areas and soil units – and to combine these effectively with human-made administrative data collection units. Thus a GIS can provide a link between the decision-maker's viewpoint and the natural boundaries of a problem (Fedra 1993) (see Box 9.3-2).

In spite of considerable interest and demand, current GIS technology is still limited in its applicability for environmental decision-making. First, spatial databases for any given region are frequently very large, requiring large system resources and highly trained personnel. Second, most early developments of GIS technology were orientated to produce high-quality cartographic products as a priority, giving less importance to modelling and data analysis issues important in the environmental field. For this reason also, systems tend to be designed with the GIS specialist in mind, and they tend to be complex. Users commonly note 'lack of user friendliness', 'slowness' and 'unreliability'.

Another drawback with current systems is that they cannot represent or process information of an uncertain or variable quality. A further restriction on usefulness is the lack of standardization of internal structures and access methods. No standard spatial access protocol like SQL is yet on the horizon, so it may be some time before the heterogeneously distributed GIS needed for decision-making becomes a reality.

This tendency has been changing lately with the development of simpler GIS systems with friendly interfaces, for the use of non-specialists interested in incorporating spatial analysis within their own work. This tendency is also improving in the integration of systems and their capacity for exchanging data.

There is considerable research into GIS and their applications, and a number of journals dedicated to the subject, such as *International Journal of Geographic Information Systems*, *Geojournal*, and *Cartographica*. A number of trade magazines provide useful information on GIS software and related hardware, and often feature consumer reports. Popular magazines include *GeoInfo Systems*, *GIS World* and *GIS Europe*. Basic text books on the subject are numerous and include Aronoff (1989), Burroughs (1989), Tomlin (1990), McGuire *et al.* (1988), and Antenucci *et al.* (1991) and Miller (1994), both of which provide a number of examples of applications relevant to biodiversity. A review of GIS and databases for vegetation change studies is given in Skole *et al.* (1993).

9.3.1.3 Management and integration of text

The recording of biological and environmental phenomena still relies heavily on a descriptive (narrative) approach that can only be captured in text form. For example, the best description of a protected area is likely to be a narrative describing its floristic and faunistic characteristics.

The basic tool for producing text is and will continue to be the word processor. In the past, however, scientists have been reluctant to rely too heavily on word-processed documents because they are not as easily queried or updated as database tables. Their main use has therefore been limited to reference material that is not likely to change (site descriptions, for example).

For several years software tools have been available to increase the utility of digital text through the application of text indexing that allows access to the text based on keywords, facilitating the location of relevant text. These tools are as flexible as the more popular database management systems, though the contextual form of free text can often be more informative. Such tools have been used very successfully in the past to retrieve data, metadata and reports. Nevertheless, their use is not widespread and remains limited.

With the advent of network communications, we are seeing a renaissance in the use of text as a form of information storage and retrieval. Network tools and services such as email, Gopher, WAIS (Wide Area Information Server) and WWW (World Wide Web) are ideally suited to the querying and retrieval of text. Tools such as WAIS are particularly powerful systems that allow Internet users to query a wide variety of information sources based on word searching.

Box 9.3-1: Selected biodiversity database projects.

FishBase

Description: A global database on fishes developed by ICLARM and FAO with support from the European Commission. The database presents information on all aspects of ichthyology and of fishes as resources, notably on their nomenclature, distribution, ecology, reproduction, growth and mortality.

Where used: More than 63 researchers from 18 countries have contributed to the collection and validation of FishBase data holdings. Particularly active countries are Australia, Bangladesh, Ghana, Hawaii, Malawi, Malaysia, Mexico, Peru, the Philippines and Vietnam. *Availability:* The full FishBase software package (with pictures) currently requires about 100 Mb of hard disk space, and has only been provided to close collaborators (around 20 institutions). Most users will prefer to wait for the CD-ROM which was released in 1994, and will be updated regularly.

Contact: R. Froese/M.L.D Palomares/D. Pauly, International Center for Living Aquatic Resources Management.

Biodiversity Information Management System (BIMS) [formally MacKinnon-Ali Software System (MASS)]

Description: Relational database for monitoring the conservation status of species, wildlife habitat and protected areas.

Where used: Most Asian countries; used to determine conservation priorities at institutions in Bhutan, China, Indonesia, Thailand and Vietnam.

Availability: User manual is provided; continuous support is not. Various aspects of BIMS are still under development (e.g. data validation, user interface design, ease of use, packaging). To realize the full potential of BIMS, an intensive period of training is required.

References: MacKinnon (1992), MacKinnon (1994).

Contact: John MacKinnon, Asian Bureau for Conservation.

Botanical Research and Herbarium Management System (BRAHMS)

Description: An information system for storing and processing botanical data, primarily that derived from or relating to botanical collections. The system has been developed for use by professional botanists, for general herbarium management, and for those working in disciplines such as ecology, forestry and conservation science.

Where used: Various locations in Africa and Central and South America.

Availability: The system is supplied with full technical documentation and user manual. A module known as RDE is also provided for Rapid Data Entry. BRAHMS is only supplied via a formal collaborative arrangement, in which installation, training and support are provided.

References: Filer (1994).

Contact: Dennis Filer, Oxford Forestry Institute.

Environmental Information System (ENVIS)

Description: A suite of packages aiding retrieval of information on government and non-governmental environmental activities.

Where used: Indira Gandhi Conservation Monitoring Centre, New Delhi.

Availability: The system is currently not available outside of IGC MC. However, plans are being made to release data holdings over the Internet, and to provide run-time versions to other organizations.

References: WWF-India (1994).

Contact: S.K. Puri, Indira Gandhi Conservation Monitoring Centre.

The trend toward the use of WWW will make the integration of text and data more powerful as it encourages the use of text not just as a format to hold information and data, but also as a means of helping users find and use data. For example, users of a WWW page may selectively retrieve information based on related text describing sources and quality. These new tools, coupled with the very large user base provided by the Internet, have empowered organizations with large text-based archives to become active in the dissemination of information and data.

9.3.1.4 Tools to computerize existing data

When dealing with large amounts of data, information retrieval can become extremely difficult. Modern tools such as computers provide assistance in accessing data, but the problem of converting existing data into electronic form remains. Fortunately, there are several tools that facilitate the conversion of analog data (paper, graphics, images) into electronic form, thereby reducing the need to enter them manually using a computer keyboard.

Box 9.3-2: Added value of a national environmental information system.

Eighty major development projects in various sectors in Lesotho were reviewed by Tveitdal (undated). Every project needed geographic information as a basic input, and 50 of the projects produced geographic information useful for environmental assessment and resource management. In all 80 projects, a great deal of time and money were used in the collection and integration of incompatible data from various sources. Moreover, in most of the 50 projects that produced environmental or resource information, the information was simply discarded at the end of the project. In the best cases, it was filed in the form of reports. Upon completion of all 80 projects, the general availability of environmental information in Lesotho had not been improved at all.

If a national Environmental Information System (EIS) had been established at the outset, project-orientated information could have been accumulated in a systematic way and shared among projects, increasing the value of information many times over and reducing project costs. An EIS would have also increased the overall value of environmental information in Lesotho, resulting in better resource management and environmental protection in the future.

The conversion of text on paper into electronic form can be done, for example, using a 'scanner' that converts written lines into a graphical image. This image can be converted into text using optical character recognition (OCR), and, if the text is laid out on paper in a standard way, it can then be converted into a data file. However, not all text can be converted into a computer-readable format accurately, and handwritten text cannot be recognized by commercial software. Problems can also arise during the OCR process if printed text uses too many different fonts and sizes.

Scanning devices range from very simple desktop devices to extremely sophisticated professional scanners. The devices can also be used to convert printed images, graphics and maps into electronic form. The resulting electronic images – in particular, maps – may be extremely large files, and their manipulation requires specialized software packages. When scanning images and/or maps, consideration must be given to what kind of device will represent the resulting electronic image as this may dictate the resolution and thus the type of scanner required. If the scanned maps are to be used within a GIS, points on the map will need to be accurately geolocated, and one may also need a considerable amount of identification of features and the addition of attribute information. Maps can also be manually digitized, which involves the physical

tracing of lines on a map after the map has been set on a digitizing table.

When scanning or digitizing any data, it is critical to validate them (just as is done when data are keyed into a computer). To maintain data quality, nothing should be added to a database without being checked for reliability. In addition, while the conversion of data from remote-sensed imagery to maps can provide a substantial amount of valuable information, it can also introduce errors. It is therefore important to require some in-the-field qualification/quantification of remotely-sensed data – a process called ground truthing – before making any major decisions based on these data.

9.3.1.5 Harmonization tools

Combination of data from different sources, or from different environmental sectors, depends more on the data themselves and how they are collected and stored, than on hardware or software. Effective combination requires a knowledge of the measurement techniques, standards, classification systems, quality assurance methods and terminology used in obtaining and describing the information. This re-emphasizes the importance of adequate documentation of data sets (9.2.4.3), and the value of metadata (9.2.4.4) in locating those data that can be usefully combined. Most frequently, harmonization relies on the use of whatever computer tools are available by individuals familiar with the data concerned. Combination will depend on key fields present in both data sets, which may be geographic or taxonomic, and so on.

Simonett (1992) identified a range of issues that should be examined in merging remotely sensed data with data from other sources, including:

- the quality of the various data sets, and the effects of data quality on error propagation;
- establishment of physically-based or index relations between remotely sensed data and other data, to enable data substitution to be employed; and
- the degree to which missing data can be tolerated.

Image analysis systems (which provide tools for processing digital images deriving from remote sensing and photography) have been developed mainly as aids to the interpretation of remote-sensed imagery, but are now merging with GIS technology. Functions offered usually include geometric rectification and automated image classification. The basic differences between the very low cost systems and more expensive systems are the range of choice in automated classification, size of the image which can be handled, and the range of output choices.

In the field of biodiversity, many of the data have a subjective element and considerable uncertainty. Resulting from the intrinsic complexity and randomness of nature,

combined with finite budgets, this uncertainty cannot be entirely removed. Biodiversity conservation decisions must always be made in the presence of imperfect data. The technology of uncertainty management is therefore an essential harmonization tool. There have been recent advances in this area, employing what is called fuzzy set theory and fuzzy logic to manage retrieval in databases with subjective or 'verbal' attributes and the use of spatial uncertainty zones and error propagation techniques to present visualization of relative uncertainty to decision-makers in the form of an uncertainty map.

Modern metadatabases and other information servers are beginning to use hypertext linkages and multilingual thesauri to form flexible relationships between the information descriptors, which allows for effective intelligent guidance to the decision-maker on locating the appropriate information, its quality and accuracy, and its appropriateness to models. Although at present the information available over such networks is very variable, such information sources are key to an effective intelligent human interface to an environmental decision support system.

9.3.1.6 Environmental thesauri

Sources of information can be described and referenced through a catalogue or a metadatabase by assigning descriptor keywords to the sources. The use of a controlled vocabulary to describe data sets has the following advantages:

- it ensures a consistency of spelling around the world;
- it provides cross-linking and referencing through a hierarchy of categories and a network of related terms; and
- it provides standard lists in multiple languages (e.g. English, French and Spanish).

Good thesauri will not only deal with synonymy (such as wood and forest, or national park and *parc national*), but will also store a hierarchy of categories. For example, a geographic thesaurus would enable a search on the keyword 'Africa' to score a hit if it located an information source with the keyword 'Kenya'.

A conclusion of the International Society for Knowledge Organisation (ISKO) Conference of 1994 (Rybinski *et al.* 1994) was that the range of existing environmental thesaurus initiatives was not desirable because they lead to an uncoordinated and confusing plethora of choices for the thesaurus user. Collaboration between these initiatives was required so that at the minimum a common thesaurus structure could be agreed upon.

The major environmental thesauri are:

- CAB International Thesaurus for Agriculture and Environment
- The Consortium for International Earth Science Information Network on-line catalogue system
- EEA, Trilingual Thesaurus for the Environment
- INFOTERRA, Thesaurus of Environmental Terms
- Japan Information Centre for Science and Technology (JICST) Thesaurus
- Umweltbundesamt Environmental Thesaurus

9.3.1.7 Other evolving tools

Several other areas of information technology are evolving rapidly today, and some may prove very useful to environmental decision-making. Recent advances in telecommunications allow the transfer of very high volumes of digital data between different locations. In theory, it would allow the creation of a globally distributed database (although so far none has been created). In practice, at the very least, it has permitted the efficient movement of large volumes of information.

New knowledge-based or 'expert' systems are intended to give decision-makers the reasoning power of a large group of experts who have individually contributed their knowledge. These systems should help environmental decision-makers locate appropriate information (where the complexity of the data is too great for any one person to 'know') as well as provide expert reasoning in the decision-support models.

Global Positioning Systems (GPS) utilize a series of satellites to allow the determination of positions on the Earth's surface in terms of their latitude, longitude and altitude. The units that achieve this are referred to as GPS receivers and can be small enough to be hand-held or used in moving vehicles. These are obviously important aids in determining the location of sample sites or biological observations, which in the past was often accomplished by marking maps or air-photos – an error-prone process, especially in dense forest or featureless terrain. Absolute accuracy on the ground is normally limited to 100 metres, but relative accuracy using 'differential' methods from a nearby accurately surveyed point can easily be a few centimetres.

GPS receivers can be linked to digitizing software, allowing data capture in the field and this process is becoming more popular, particularly in areas where very few data already exist and accurate locations are required (to the nearest 100 metres). Improved accuracy normally means increased cost, with highly accurate units (which utilize several transmission frequencies and many 'channels', i.e. satellites) costing a few thousand US dollars. Less accurate units suitable for field work cost a

few hundred dollars. Analysis software is also needed, and in some cases incurs an extra charge.

New applications based on graphical user interfaces and standardized menu systems are becoming much easier to use than older systems, integrating many of the functions that previously required separate programs and new interfaces to learn. Many communication functions are being built into the operating systems on which computers run, further simplifying the installation and use of networked applications. These tendencies facilitate integration and effective use of a wide variety of tools in biodiversity assessment and management activities. Many of these applications do require more powerful hardware, but the increased cost of equipment should be considered in the light of cost savings from reduced training requirements and the more limited potential of less sophisticated solutions.

9.3.2 Reporting, analysis and modelling tools

The products of information management range from very simple indexes and indicators to complex environmental or spatial models. The applications and use of these products will also vary – from efforts to better understand the natural system to the evaluation of the impact on the system resulting from a specific action, prediction of the natural or human-influenced evolution of a natural system, or the development of flexible decision-support systems in environmental management.

All the data management tools described in the previous paragraphs have output capabilities that allow for the selection of material based on defined criteria. For example, RDBMS records can be selected to meet certain criteria and be sorted and presented in a variety of formats. In a GIS, a range of maps can be generated and overlaid to demonstrate certain landscape features and then be printed out as part of a report (possibly with annotations added from attribute files).

Environmental modelling has developed considerably since the early efforts of Volterra (1926) to model competition between populations. Not all areas of analysis related to biodiversity have the same level of development: some natural processes lend themselves to analysis with currently known technologies. In other cases we have not been able to develop a sufficient level of understanding of the system, and an analytical approach commensurate with the challenges placed by biodiversity management. Nevertheless, this field has benefited greatly from the easier access to and power of the present breed of computer equipment, allowing an easier and more cost-effective use of these analyses at several scales, from field level to national level.

As demand for analysis and modelling grows, so does the demand for more data, at different scales, with better precision and quality. Data availability and quality will in most cases determine the type of analysis that can be done.

In most cases, trying to implement too complex an analytical approach – with limited data or data of questionable quality – might prove to be a mistake. In these cases, a simpler approach based on the use of more basic database outputs, indices and the advice of experts may prove to be more useful and viable.

9.3.2.1 Modelling physical and ecological processes

Models of the physical environment represent the most advanced area in environmental modelling to date. Such models include analyses of hydrological systems, atmospheric systems, and land surface and subsurface processes. Present modelling efforts range from simpler non-spatial prediction models for water flow to complex dynamic models that explicitly include a spatial topology.

One important type of analysis is the extrapolation of spatial data, principally topography and climatic variables (see Box 9.3-3). The digital terrain model and climatic layers generated through this process can be used in a great number of analyses related to biodiversity – for example, for predicting the potential distribution of a species, or in estimating areas of high fragility based on erosion potential.

Biological and ecological models focus on obtaining a better understanding of the structure and dynamics of natural systems. These kinds of models have already been discussed elsewhere in this volume.

9.3.2.2 Risk and hazards

Concerned with the analysis of interactions between humans and the natural world, these are among the most frequently used environmental analyses. So far they have focused primarily on the area of impact assessment – estimating the impact of development projects on the environment and on biodiversity. These assessments take into consideration effects on land use and land-use change, socioeconomic processes, quality of life and so on, integrating a wide array of information under a common framework, usually provided by a GIS.

Risk and hazard analyses require an integrated information system that will include relevant information on the physical environment (topography, climate, soils, etc.), biotic environment (species distribution, distribution of ecosystems, habitats, etc.), socioeconomic issues (including population growth and demand), and the entire area of natural resource use and conservation.

9.3.2.3 Modelling and policy-making

The development of decision-support systems in the environmental field at the level of planning and policy has been advocated for some time. Nevertheless, there are a limited number of successful implementations. This is an area where more effort is needed in the development of novel approaches to better integrate large amounts of data

of different types in a framework that will facilitate the analysis of complex problems by different types of decision-makers, from citizens to government officials.

A key issue related to the Convention on Biological Diversity is that of defining priority areas for the conservation and management of diversity. One effective approach to regional priority-setting has been that of relying on experts on a particular region to identify top conservation priorities within the larger area. These experts make heavy use of a previously assembled GIS-based database on the region's physical and biotic environment, land use, population pressures, natural resource use, and other variables (Olivieri *et al.* 1995). The end result is a consensus among a broad array of experts on specific areas of high biological value, threats to their future, and opportunities for conservation within the region.

9.3.3 Networks

The use of stand-alone computers within an information management facility can be greatly enhanced through the development of Local Area Networks (LANs). This not only allows the sharing of resources such as printers and file storage facilities, but also provides the opportunity for exchange of documents, messages, images, sounds, spreadsheets and databases. LANs can also use telecommunications facilities to link to other networks and, with the growing awareness of the importance of information and communications, wide area connectivity has become a primary issue. In more and more cases it is now expected that computers *should* be networked in some way, able to communicate with any other computer similarly connected whether in the same office or on another continent.

However, networking depends on the efficacy of national telecommunications infrastructure. Despite rapid technological advances and decreasing costs, telecommunications facilities have not kept pace with developments in computing (Jensen 1995). Demand for facilities to exploit sophisticated applications remains largely unsatisfied for many users, even in developed countries. This is almost always because of the fragility of the 'last mile' from the public telecommunications operator to the user. This situation is particularly important in developing countries where this is the most important limiting factor for the interconnection of the existing computing capacity. Africa, for example, has an average phone density of one line per 250 people, which represents less than 1% of the density in the advanced industrialized nations. Some countries have less than one line per 1000 people. Furthermore, in most developing countries, communication costs are still very high, phone lines are unreliable for computer communication, and waiting time for new connections is over-long (5–10 years). This situation is not likely to change in the near future and changes will most likely not occur quickly. As a result, we

Box 9.3-3: Bioclimate prediction model.

Bioclimate Prediction System (BIOCLIM)

Description: Software that uses previously generated climate surfaces to generate climate estimates for sites where a species has been recorded; generates a climate profile for that species, and evaluates geographic areas in terms of their climatic similarity to the profile.

Where used: Mainly Australia, although suitable climate surface databases have also been developed for New Zealand, Papua New Guinea, Madagascar, Guyana, Africa and other areas.

Availability: A basic user manual is provided; continuous support is not. System was converted from a mainframe version to PC and does not meet commercial standards in terms of user interface design or ease of use. Good background on GIS is needed to realize the potential of BIOCLIM.

Contact: Henry Nix, Centre for Resource and Environmental Studies, Australian National University.

must be careful in assessing the value of networking in each country and look for those technical solutions that will allow us to circumvent these limitations.

9.3.3.1 Connecting to networks

Until relatively recently, most interaction between computers on different sites was *direct dial*, involving a direct modem/phone connection between individual machines. Terminal emulation programmes resident on both local and host machines allowed the computers to 'talk' to each other, and software resident on the remote host was then used to transfer messages and files, and to access other available services.

This system requires the user to be on line for long periods of time, so more recently *client/server systems* have been developed which use the capacity of local hardware as far as possible, to automate network functions, to integrate transparently with locally run applications, and to maximize efficient use of communications facilities.

It is often more cost-effective for a group of users to share the use of a local computer host (often called a *node* or *server*) which provides a 24-hour service to allow users to send and receive communications at their own convenience. The group of local users effectively splits the cost of maintaining the necessary linkages.

Services have now been installed by many public telecommunications operators which allow the use of local phone calls to connect computers to a *packet switched data network* (PSDN). Once connected to the local network, commands can be issued to link the user's computer to any other system connected to the worldwide network of PSDNs. These networks charge

mainly for the quantity of data that passes through the network.

An alternative to the demand-based temporary dial-up link over voice phone lines to a remote network is a *dedicated leased line* connection. A dedicated link has the added advantage of enabling members of other remote networks to access your system directly at their convenience, should this be desired. The maximum number of users able to share a line varies depending on the type of line available and the applications being used. While many users can make use of a slow link for electronic mail (which does not require interactive response from the user), sophisticated operations can become frustratingly slow unless faster (and higher costs) links are applied.

Connectivity in many developing countries is limited to email because of slow or unreliable connections. Although present technology allows connections at a speed of 28 Kb/sec over telephone lines, in practice the interference common on dial-up analogue lines can limit the potential speed substantially, especially during the rainy season when unmaintained cables can be subject to the effects of moisture.

9.3.3.2 Internet

The best-known computer network is the Internet, which is in fact a large collection of networks using a common communications protocol – Transmission Control Protocol/Internet Protocol (TCP/IP). Information can be communicated across these networks using a range of different tools (Table 9.3-1).

While in some parts of the world telematics activities are still virtually non-existent, users in many countries are taking advantage of the wide range of information available through computerized networks (see chapter 9.4). One hundred and fifty-nine countries now have some form of connection to the Internet (Figure 9.3-2): the number of users was estimated at over 30 million by mid-1994 and continues to grow at 12–15% per month. At this rate, it is expected to reach 200 million by the year 2000. Where the precise nature of planned national and regional information infrastructures has yet to be established, the exponential growth of the Internet indicates that it will be the model from which other networks will evolve.

The Internet is experiencing exponential growth in the number of networks, number of hosts and volume of traffic. The number of host computers has increased from 200 to 5 million in 12 years (between 1983 and 1995) (Cerf 1995). The Internet now encompasses an estimated 50 000 networks world-wide, about half of which are in the United States.

The Internet breeds the electronic equivalent of the thief who looks for open windows and doors, but security is only a real problem for dedicated lines (see 9.3.3.1). The most robust form of security is to install a 'firewall'. This

is a computer set up between your computer network and the Internet through which all traffic is diverted. However, the issue of security is too complex an issue to discuss in full here. Service providers should be able to advise on this.

The growth of the Internet and its distributed architecture has encouraged the integration of local dial-up networks. Most of these networks offer at least email access to Internet and in many cases other services such as FTP and Gopher as well. They also provide their own tools for news and information services, conferences, database access, fax and telex. Because they offer a local dial-up connection, in many cases this is the easiest and most cost-effective way to link to the Internet in developing countries.

ECONET, established by the Institute for Global Communications (IGC), is one such network which provided email access in developing countries in Africa and Latin America long before Internet was accessible. The Association for Progressive Communications (APC), a consortium of more than 50 international member networks (among them the IGC networks) reaches some 30 000 people in more than 130 countries on themes closely related to biodiversity.

With the global interconnection of networks, contact can be made with millions of others on the various university computer networks that form part of the Internet world-wide, the APC, BitNet and other networks, as well as the commercial users on other business-related networks such as Dialcom, GeoNet, CompuServe and MCI Mail.

9.3.4 Other information dissemination tools

Traditional data dissemination in the form of printed material remains the most common approach today. Printed materials range from published books to posters and maps and from customized reports to standard products. With the advent of DeskTop Publishing Systems – which allow text, graphics, images and numeric values to be reproduced and moved around easily – all of these printed materials have become easier to develop in recent years.

9.3.4.1 Diskette and CD-ROM

The exchange of information between computers by the exchange of diskettes, and the marketing of information on diskettes, has been widely used for many years. This means of data dissemination is easy and direct, and it does not require a major investment in equipment to produce or to read. It is also a solution that depends on the passing of a diskette by hand – rather than over networks, which may not work in some parts of the world because of poor telecommunications systems.

Applications range from the simple exchange of data files to marketing diskettes that not only include data, but also applications for helping the user access and apply the

Table 9.3-1: Network tools and applications.

Tools that use computer networks include:

- **Electronic Mail** (email). This tool enables users to send messages as electronic text to one or more users working on another computer. It can also be used to automatically request identified documents.
- **LISTSERV**. This is an extension of email, where users decide to be on a particular mailing list for regular receipt of information or to participate in a discussion forum.
- **USENET**. This application is similar to the previous one, the main difference being that subscribers have access to electronic bulletin boards, and they can read the messages from the board itself without having to receive any messages.

Some of the more popular Network Information Retrieval (NIR) tools include:

- **Telnet**. This tool enables users at one site to connect to and use a computer located at another, remote site. To use Telnet, one generally needs an account at the remote site, but there are exceptions where a ‘common account’ for external users is available.
- **File Transfer Protocol (FTP)**. A powerful data-exchange tool, FTP enables users from the same site or from different sites to access computer files and browse through them or bring them into their own computer for analysis. There are several tools to help FTP users find the data they need. One, called ARCHIE, locates files at remote sites by filename search.
- **Wide Area Information Server (WAIS)**. This is a utility tool from the network that enables users to retrieve information by searching indexes of databases.
- **GOPHER**. Gopher locates and retrieves information resources from other computers on the network through the use of a graphic interface. Its use is quite straightforward, and information can be located independently of the site where it is housed.
- **Veronica**, acronym for Very Easy Rodent-Oriented Network Index to Computer Archives is a software tool for searching the Gopher-space using keywords. A list of Gopher sites that house information related to the keyword can be retrieved by Veronica.
- **World Wide Web (WWW)**. WWW retrieves resources via an ‘intelligent text’ (called hypertext), which enables the user to browse information presented by a WWW server, ‘clicking’ on key words to retrieve further information. WWW supports the display and transfer of images, text and sound. It is an excellent way for organizations to present information in a structured manner to a very large audience.

information. Beyond data and text, diskettes can also hold simple graphics, which can be incorporated into their applications.

This general strategy for data dissemination received a significant boost with the recent development of CD-ROMs. These provide definite advantages over traditional diskettes, including a very large storage capacity, long life, and a ruggedness meaning that they can be exposed to shocks and electromagnetic fields. CD-ROMs have one drawback, however: they require special equipment both to enter and to read their data. This disadvantage may be outweighed by the additional data-holding capacity, which includes the ability to include large map and photographic files as well as video. There has been a rapid increase in the availability of information on CD-ROM in recent years. In regions where access to networks is difficult or expensive, this technology can play an important role in the dissemination of biodiversity information.

A major innovation in information dissemination is the use of ‘multimedia’, in which a combination of computer tools is used to present text, pictures, videos and sounds in an integrated format. Multimedia techniques have an advantage in that the non-expert user can easily access and navigate the complete range of information. CD-ROMs are a perfect medium for distributing multimedia applications given their high data capacity.

9.3.5 Selection of software and hardware tools

The fast development of computer technologies – both hardware and software – has also facilitated the rapid development of computer tools. These tools are becoming more accessible, more powerful, and easier to use. They require less training and software has become extremely user friendly. Despite this progress, current commercially available software will not necessarily respond to the specific requirements of biodiversity information management.

Figure 9.3-2: Network connectivity world map, February, 1995.

The development of tools is driven by demand – usually commercial demand – which means that the research and development effort is focusing on sectors with specific needs and constraints that do not necessarily reflect those found in the field of biodiversity information management. As a result, the range of tools on offer is limited, as is their ability to fulfil our specific requirements. In many cases we settle by adapting tools that were developed with a quite different set of objectives and constraints in mind. The demand-driven tendency means that most tools are developed in a few dominant languages, usually in English, limiting their full use in the developing world.

In some cases it may be necessary for users to consider the option of developing their own tools to complement the general ones that are widely available. Although superficially an attractive alternative, it is often a difficult one to pursue, and only in exceptional circumstances can a local institution do this in a cost-effective way. The rapid changes in technology and the need to keep the tools compatible with existing and emerging data formats and other tools, require a constant development and support effort to ensure the adequacy of the tools over time, a task that few institutions can justify with their own demand. One answer may reside in pooling demands for specific tools

at a national or regional level, ensuring a larger user base that can share development, support and training costs over time.

The first question when considering the development of a new tool is whether or not an appropriate one already exists. The computer network (see Chapter 9.4) can provide considerable assistance with this task. Considerable thought should be given to deciding whether an existing tool will require more work and expense (to change data formats, for example) than it ultimately will be worth. In addition, today's market is evolving so rapidly that tools may become obsolete after just a few years. One also should avoid creating dependencies on other parties (for training or maintenance, for example) that may become problems in the future.

9.3.5.1 Selection of computer software

There are many factors to be considered when buying software. In most applications it is more important than the hardware, although often the hardware already exists and the software must be adapted to it. Software may either be acquired as an off-the-shelf product (assuming the software can be run on the available hardware), or a new package can be developed specifically for the application in mind (or perhaps modified from an existing package to meet

specific requirements). The arguments for and against both these approaches are discussed in FAO (1986). Because many software packages are written for a specific type of hardware, knowing which computers will be used to run the application will eliminate some software packages from consideration.

9.3.5.2 Selection of computer hardware

If new hardware is required, then the best match between the system needs, the available resources, and the various hardware options needs to be determined. Establishing criteria for sizing applications is a complex process and is discussed at length in Bentley (1984). However, two preliminary, basic questions can be used to narrow down the hardware choices – the identification of the number of people who need *simultaneous* access to the data, and an assessment of how much data will need to be managed.

If single-user access is adequate, a microcomputer (PC) is probably the best choice, unless a very large amount of data needs to be handled (Fairhead (1992) provides an excellent, comprehensive guide to the technical options available for PCs and discusses their practical implications for the user). For simultaneous access by more than one person, a workstation is a better choice. If the plan is to store and manipulate a large volume of data, the options to consider include networks, minicomputers and possibly client-server architecture.

9.3.5.3 The selection process

The selection and purchase of both software and hardware follow a similar path, which can be broken down into the following eight stages. These stages are discussed in detail in Wright (1988).

- Decide what is required of the system.
- Carry out a feasibility study.
- Prepare an accurate specification of needs, which includes:
 - the system’s objectives and functions
 - the work load to be executed (volumes of transactions to be input, processed, output, stored)
 - performance targets
 - special requirements in hardware, software and support services
 - operational requirements (availability targets, etc.)
- Invite tenders, based on the specification.
- Evaluate tenders, based on criteria that would include:
 - whether the solution proposed fully meets the specification

- price
 - additional useful functionality proposed
 - ease of use
 - follow-on services (such as upgrades, maintenance, technical support)
 - product reputation
 - vendor reputation
 - product durability (including likely lifetime and ‘expandability’)
 - compatibility with other products
 - comparative performance (see, for example, Fairhead 1992)
- Prepare a short-list based on the tender documents.
 - Carry out acceptance tests to ensure that the system meets the specification.

9.3.5.4 Selection of database management systems

All databases, whether they are simple card index programs or full-blown professional development systems, store information rather like record cards in a filing cabinet. All database management systems allow the entry of new records, and changes to be made to existing ones, through screen forms (which can usually be customized). They also allow searches to be made for specific records, sorting of records into different orders, and the design of reports which print details of the records selected in the order desired by the user.

Most databases today are ‘relational’ in one form or another (9.3.1.1) and the majority follow a non-programmed approach by getting the user to complete on-screen forms or choose menu options. The more sophisticated databases are programmable, allowing the user to handle more advanced data structures and to tailor the resulting database to personal needs.

Some of the most important options to consider when deciding which DBMS to select are:

- whether a ‘relational’ capability is required (to combine data from two or more tables using key values)
- data validation capabilities
- file import/export formats supported
- form (screen display) designs, and the capacity to modify them
- indexing capability
- programmability

- adequacy of the report designer
- SQL and client-server architecture

9.3.5.5 Selection of geographic information systems

Several hundred commercial vendors can provide GIS software packages, and consequently a very wide choice of functionality is available. The two basic approaches are *raster*, in which the data are represented by a huge matrix of grid cells, and *vector*, in which the spatial data are kept as a series of connected line segments (arcs). Raster GIS are generally cheaper and simpler, and can provide good spatial modelling capacities and are thus often applied to regional planning and assessment. Vector-based GIS software is more complex and defines the data with much more detail and spatial accuracy. Application is widespread, particularly where there is a need for complex analysis and accurate delineation of boundaries, especially when high-quality cartographic production is involved. These systems also have higher requirements in hardware and trained personnel. Many systems now offer a mixed approach and are able to handle both kinds of data.

Geographic Information (GIS) packages offer a vast array of spatial analysis functionality, therefore the requirements should be defined very clearly prior to purchasing a GIS. For example, will the GIS be used for modelling or for simple two-dimensional map design? This type of consideration will greatly affect the choice of GIS – and its cost.

Many of the longer-established products have built up an international user base that collectively attends regular local, regional and international conferences. Several now have their own email list servers and news groups over the

Internet and CompuServe to exchange ideas and provide answers to problems. International or local support for the product may be provided by the manufacturer or distributor as part of the cost of purchase or as an additional maintenance contract.

For a complex software package, support, both as training and continued technical support, is an extremely important factor in the success of new installation. Different distributors are strong in different areas of the world, and consequently the support a user can expect varies with their locality. Local support and an established user base should be an important consideration when reviewing the possible options for the implementation of a GIS.

9.3.5.6 Existing biodiversity application software

Over the last decade, many institutions holding biodiversity information have applied information technology specifically to manage their data in efficient ways. The resulting tools, which can broadly be defined as biodiversity application software, fall into the following rough categories (see also Box 9.3-4):

- Species information systems. Sources of information on particular life forms or taxonomic groups. Somere released as multimedia packages containing ‘finished product’ information sources (e.g. distribution maps, photographs, taxonomic nomenclature).
- Biodiversity assessment tools. Used to gauge the distribution and status of species, communities and habitats. By relating species occurrence to underlying habitat, some systems permit rapid biodiversity assessment using predictive techniques.

Box 9.3-4: Selected biodiversity application software.

ALICE Biodiversity Database System

Description: A family of programs for biologists designing and building their own checklist or biodiversity database. Intended primarily for data capture, ALICE also has species-orientated query facilities and pre-defined reports. Applications include writing checklists, building species inventories, and developing species identification systems.

Where used: The International Legume Database and Information Service (ILDIS), involving collaborating institutions in more than 20 countries; UK poisonous plants database; species inventories in several protected areas.

Availability: The Alice Software Partnership has a professional relationship with users. In exchange for a licence fee, programs are provided with documentation, user support and updates. On-site guidance for installation, use, and how to develop your own database, can be arranged.

References: ALICE (1990).

Contact: Robert Allkin, ALICE Software Partnership.

BG-BASE 4.0

Description: Database application designed for managing biological information in four categories: taxonomy, distribution, conservation and collections management (living and preserved). Suitable for a variety of institutions including botanic gardens, arboreta, zoos, university campuses, horticultural societies and private gardens.

Where used: BG-BASE has been installed at 53 locations in eight countries, including Arnold Arboretum, Harvard University, USA; Royal Botanic Gardens, Kew, UK, National Botanic Garden, Harare, Zimbabwe, and WCMC.

Availability: BG-BASE has been tuned to users' needs over a 10 year period. A comprehensive user manual is provided (currently under revision), and a regular newsletter is produced containing news from BG-BASE users, technical tips, and details of new locations using the system.

References: O'Neal (1989).

Contact: Kerry Walter/Michael O'Neal, BG-BASE Inc.

Biodiversity Data Bank 1.0 (BDB)

Description: Desk-top tool for storing, analysing and mapping biodiversity data.

Where used: National Biodiversity Data Bank, MUIENR, Uganda.

Availability: Full technical documentation is provided; however, no user manual has yet been written; continuous support is not available outside Uganda. BDB is written professionally in terms of user interface design, ease of use, and data validation, but would require *in situ* training until a user manual is produced.

References: Reynolds (1993).

Contact: Jake Reynolds/Derek Pomeroy/Herbert Tushabe, Makerere University Institute of Environment and Natural Resources.

Biological and Conservation Data (BCD) System

Description: Data management package that facilitates the collection, distribution and exchange of information pertinent to the preservation of biodiversity.

Where used: At Natural Heritage Programmes (NHPs) and Conservation Data Centres throughout the USA, plus Canada, Puerto Rico, and 13 Latin American countries.

Availability: Full training programme encouraged via collaborative agreement with TNC.

References: TNC (1992).

Contact: Richard Warner, The Nature Conservancy.

CISIG Geographic Information System

Description: A Geographic Information System designed to work at the field level: PC-based, multilingual (currently in English, Spanish, Portuguese), user friendly, analysis orientated (raster based), includes several modules tailored to needs of biodiversity analysis and management.

Where used: Installed in around 200 institutions, mainly in developing countries.

Availability: CISIG 3.0 available 9/95 for a price of US\$200 or through Conservation International's Grant Programme. The system is supplied with full manual in any of the three languages, technical support available from Conservation International and through the SIGNatura Network.

References: Conservation International (1994).

Contact: Silvio Olivieri, Conservation International.

Countryside Information System

Description: Stores, analyses and presents data for each 1 km square of Great Britain and Northern Ireland. Intended to help policy-makers and researchers obtain information about the British countryside in a standard and user friendly way.

Where used: UK Department of the Environment, ITE (Merlewood Research Station, Monks Wood).

Availability: The Countryside Information System is supplied as part of a commercial-quality package that includes technical documentation, user manual and support.

References: Barr (1993).

Contact: Robert Bunce, Institute of Terrestrial Ecology.

Expert Center for Taxonomic Identification

Description: A project to create a centralized resource of world-wide biodiversity information, via a network of contributing partners. The project encompasses software for entry of species information, species identification, and multimedia species presentation.

Where used: Queensland Museum, Australia; Smithsonian Institution; University of California; Institute of

Box 9.3-4 cont.

Taxonomic Zoology, Amsterdam; Shikoko University, Japan; many other institutions concerned with taxonomy in Europe and world-wide.

Availability: Partners for the ETI programme are actively encouraged. Each enters into an agreement with ETI to provide species data on a suitable media (including special purpose software such as *Linnaeus II* provided by ETI). In return ETI promises to distribute the results to partners regularly on CD-ROM.

References: Schalk (1992).

Contact: Peter Schalk, Expert Center for Taxonomic Identification.

Forest Reserves of Ghana: Geographic Information Exhibitor (FROGGIE)

Description: Interactive map-based database for assessment of forest biodiversity. Developed originally to manage the Ghana forest inventory, but now being extended into a generic forest assessment tool.

Where used: Planning Branch, Forestry Department, Kumasi, Ghana; Pasoh Forest Reserve, Malaysia.

Availability: FROGGIE is currently being developed into a sophisticated visualisation tool for a variety of forest inventory data. The new version (April 1995) written in Visual Basic (DOS) comes with full documentation. It is compatible with the BRAHMS collection management software and thus is able to share data files. The availability of support structures and documentation should be carefully examined.

References: Hawthorne (1992).

Contact: W.D. Hawthorne, Oxford Forestry Institute.

RECORDER 3.2

Description: Relational database for organizing site-related species records. Aims to answer two common queries: the species inventory for a particular location; and the circumstances of a record at a given location.

Where used: Biological recording centres, research organizations, conservation trusts, museums, local authorities, and individuals throughout the United Kingdom.

Availability: RECORDER is packaged with full documentation, training and user support (e.g. a bi-monthly newsletter). The current version is also bundled with Advanced Revelation 3.1 software so that users do not have to purchase this separately. The package is continually being improved according to user demands.

References: English Nature (1993).

Contact: Rosy Key, English Nature.

WORLDMAP 2.4

Description: Graphical tool for the interactive assessment of priority areas for conserving biodiversity. Can be used to find a sequence of priority areas accounting for the maximum biodiversity as measured by species richness, higher-taxon richness and various other phylogenetic dispersion measures.

Where used: The Natural History Museum, London; National Museums of Kenya, Nairobi; biodiversity research groups in Southern Africa.

Availability: WORLDMAP is supplied with basic documentation covering installation, use and potential error messages. A sample data set is provided with the system to guide and demonstrate its potential to new users. Ease of transfer of existing data and maps to WORLDMAP format, and long-term support issues should be examined carefully.

References: Humphries (1991), Williams 1995.

Contact: Paul Williams, The Natural History Museum (UK).

- Collection management systems. Facilitate the entry, storage, querying and reporting of information on biological specimens in museums, herbaria, universities and other collections.
- Biodiversity action records/tools. Supporting biodiversity conservation in novel or indirect ways. This would include a number of the models discussed earlier (9.3.2).

With most systems, a trade-off may be observed between the geographic scale of the information holding, and its subject area. For example, a localized system serving the needs of a single institution may bring together many areas of biodiversity information, whereas a global system may for practical reasons be restricted to a single subject area.

It is difficult to define 'typical' biodiversity application software due to the wide variety of tools currently in use, so it is necessary to review a variety of systems performing

different functions and illustrating different approaches. Only then can an assessment be made of the relevance of particular systems to an individual user's needs. A key aspect of this will be the degree to which the system is *transferable* to different situations, not rooted to one project or location.

9.4 Making information more widely available

9.4.0 Introduction

In addition to working within the framework of the Convention on Biodiversity, each of the world's nations will have its own unique information management needs and priorities. There is therefore no single recipe for information access and dissemination, and countries and other users of biodiversity information should adopt individual approaches based on local conditions.

The greatest challenge in information dissemination is encouraging agencies and individuals to share appropriate data with others who need it. This can happen in a variety of ways, including dissemination through networks, magnetic tapes, diskettes, reports and maps. One should not underestimate the value of simply copying and disseminating information to those who might use it.

It is essential to build an efficient information-dissemination infrastructure as part of the development of a national information management capability. This is vital in order to ensure that those most in need of information are able to access it in a format they can use. It is also critical that those who are part of the information process can see the value and impact of the information they have contributed.

9.4.1 Exchange standards

Communication between information providers and users depends on common vocabularies and languages, which are generally expressed as standards. Standards covering the way in which biodiversity data are collected and recorded are discussed above (9.2.6). The following paragraphs outline standardization in the exchange of data.

It is obvious that transfer of data between agencies and, in particular, integration of data sets from a number of agencies is made easier by at least elementary standardization. Similarly, data users are more comfortable with standardized interfaces and other methods of accessing data.

9.4.1.1 Directory exchange standards

These standards allow users to integrate descriptions of data sets from a variety of sources, usually data directories. Directories are maintained by a range of national and international agencies. There is no one body that can enforce compliance with any particular format, so agreed standards are necessary in order that users can navigate relatively easily between directories. The NASA Global Change Master Directory has been built on one such standard.

9.4.1.2 Data exchange standards

Data exchange standards often emerge out of informal arrangements between parties who want to move data back and forth. The simplest form currently in use is called ASCII text. As long as an institution's database software permits the import and export of data in ASCII text, data exchange is possible once the list of data elements to be exchanged and their characteristics have been determined.

Data exchange standards must take into account several variables: (1) the selection of attributes to represent biodiversity or other phenomena of interest; (2) the nature and meaning of values attached to those attributes, and (3) the way in which these attributes and their values are communicated. A 'community', for example, could be represented by: its species composition, the names (from a national checklist) and estimated abundances (from a specified classification system) of each species, and a data file transmitted from one agency to another in an ASCII character format with specified characters acting as field and record delimiters.

There are numerous spatial and other data transfer standards developed or being adopted around the world. This is a very dynamic area and much work remains to be done. Many standards are based on a standard language format, such as the International Standard Organization (ISO). Translations between these standards are being developed by various software development agencies. Some data transfer mechanisms are very straightforward and can be used by anyone. For example, as outlined above, merely using some designated special character to separate different attributes of a data record is a very simple, yet flexible and powerful, way of exchanging structured alphanumeric data. Table 9.4-1 presents a list of standards most relevant to the field of biodiversity.

9.4.1.3 User interface standards

All information users, whether expert or not, expect interfaces to be simple and intuitive. In addition to providing ready access to information, the interface should allow the user to combine information in various ways and to export data for other purposes. The information should be available in the most appropriate form – whether text, numeric, pictorial, video, sound or maps – and all information should be linked through a single interface to allow fast, interactive use.

9.4.2 Presentation of information

The technology to support the presentation of biodiversity and other environmental information is reasonably well developed and is still advancing rapidly today. It is currently possible to retrieve raw and processed data from virtually anywhere in the world, if not on-line then by various media through the post. It is also now possible to access modelling and analysis tools, even to run them on another agency's computer and to bring back the derived product(s).

Table 9.4-1: Data exchange standards of importance for biodiversity information.

-
- **Spatial data:** There are numerous standards being implemented or under development, e.g. US Geographic Data Committee – Spatial Data Transfer Standard.
 - **Tabular data:** Structured Query Language (SQL) is a high-level, set-oriented, non-procedural database language for relational databases. SQL is an ISO/ANSI standard with the latest version commonly known as SQL92 (ISO 9075:1992/ANSI X3.135-1992). Most relational databases comply with this standard and many also include additional non-standard extensions to SQL92.
 - **Taxonomic data:** Standards are enforced through formal publication within the procedures set by the International Codes of Zoological Nomenclature and Botanical Nomenclature.
-

The International Working Group on Taxonomic Data for the Plant Sciences (TDWG) is developing world-wide database information standards for plant taxonomy, while the International Organization for Plant Information (IOPI) is developing taxonomic checklists of the world's plants.

The International Committee on Taxonomy of Viruses (ICTV) is developing a standardized code for virus description, the foundation-stone for a world-wide universal virus database (ICTVdB) (Green and Croft 1994).

- **Descriptive data:** The DELTA (DEscriptive Language for Taxonomy) format was designed to satisfy the need for a generalized system capable of accommodating all the different kinds of descriptive data used by taxonomists, but in an easy-to-use format. The innovators of DELTA solved the problem of how to order and analyse data of different types. Official DELTA Internet archive sites have been set up at the CSIRO Division of Entomology, Canberra (spider.ento.csiro.au) and at the Muse biodiversity server at Cornell University, Ithaca, USA (muse.bio.cornell.edu/11/software/DELTA and muse.bio.cornell.edu).

Others have developed more restricted taxon-group-dependent expert systems. A number of these, however, use the DELTA format for exchange (see also Bisby 1993).

- **Genes and molecular biology:** Many molecular biology databases use the simple but effective criterion of publication in a refereed journal before records are accepted into a database (Green and Croft 1994).
 - **Bibliographic:** The ISO 2709 is an international standard for bibliographic information interchange on magnetic tape. This Standard specifies the requirements for a generalized exchange format which will hold records describing all forms of material capable of bibliographic description, as well as related records such as authority records. Although this Standard is designed for magnetic tape, its structure may be used for other data carriers (ISO 1981).
 - **Multimedia:** The Standard Generalized Marking Language (SGML) provides a powerful and flexible standard for formatting information for processing of all kinds. The SGML is emerging as a leading international standard for preparing both hypertext and multimedia material for publication. It can also be used for interchanging database records.
 - **Software:** The ISO 9000 is a universal standard for development and maintenance of software. It includes a rigid set of conditions and a protocol to follow in software programming.
-

In general, then, it is not technology, but other factors – such as lack of agency co-ordination, poor data availability and quality, and lack of modelling or other analysis tools – that create obstacles to effective presentation of biodiversity information. To enhance presentation, those who disseminate information must consider carefully the format in which it will be presented. Different users of biodiversity information will find that information more or less accessible and valuable depending on its format. Selecting the most powerful format for your particular intended user is thus a critical first step.

9.4.2.1 Current issues in information presentation

One significant challenge is that of assessing the reliability

of a product that has been integrated from multiple data sources, such as a complex map overlay in a geographic information system. It is extremely difficult to assess, in a quantitative fashion, how errors in all the source data sets have been propagated in the final product. Most theoretical calculations show that error propagation is so severe that almost no confidence ought to be placed in the final product. This is obviously not particularly helpful in decision-making, and practical solutions need to be found. Part of the answer lies in attaching appropriate caveats to the derived product(s). Such caveats, however, are seldom welcomed by decision-makers, who prefer technical advice to be clear and unambiguous, even when lack of data and ecological understanding makes this difficult.

Recent developments in presentation tools such as three-dimensional image-processing technology and three-dimensional geographic information system modelling are at the forefront of research in meteorology, oceanography, hydrology, geology and ecology. These tools allow users to gain richer perspectives of data and their interrelationships by providing closer simulations of the 'real world'. Since environmental entities exist and interact in all dimensions, tools that assist the user visualize these will enhance understanding. For example, the ability to 'fly' down a valley and view vegetation patterns using video imagery can aid in the understanding of the influence of altitude on temperature and of slope and aspect on radiation and water distribution.

The increasing availability of digital elevation models has enabled ecologists to superimpose computer-classified land-cover types and actual and predicted distributions of individual species onto accurate representations of the land surface. It has then been relatively easy to quantify elevation ranges, aspects and areas occupied by various biological entities. Visualizing temporal changes in landscapes requires animating a time series of changes at each point. This is currently an active research area (Morain 1993).

9.4.2.2 Future needs

What is needed in the future is 'four-dimensional' modelling (including time) across landscapes and within vegetation canopies. However, neither the technology nor the necessary data are yet available. Unlike geological, atmospheric and oceanographic studies – where vertical profiles are standard attributes – ecological studies usually do not include vertical structure profiles (Morain 1993). Such modelling will help vegetation managers considerably in the future – whether conservationists or foresters.

Constraints to the implementation of existing technology include lack of basic computing infrastructure (such as stable electricity supplies, repair facilities and trained staff), inability to keep up with the pace of technological development, and the expense (both purchase and maintenance) of major software systems.

9.4.3 Information dissemination

The 'owner' of biodiversity information, along with any publisher, controls its dissemination, including timing, publication, distribution and proprietary rights. In addition, information owners have the ultimate ability to control its preservation and destruction. By and large, the issues arising from the rights and responsibilities of ownership are ethical, relating to appropriate conduct, rather than legal (Nash 1993) (see also 9.6).

Information owners, or custodians, often have legitimate concerns about how their information will be used. Will it be used for inappropriate analyses? Will any caveats on

data quality be responsibly considered? Will the proposed work pre-empt or duplicate the custodian's own efforts?

Despite these issues, the needs of biodiversity information users should be made a high priority. Consider, for example, the challenges facing a non-botanist in a developing country who wishes to identify an unknown plant of local economic potential. The country may not have a major herbarium, and there may be no plant taxonomists. All the significant collections may be in herbaria in North America or Europe. There may be no comprehensive plant checklists, let alone any plant collections. Even if such a checklist exists, it may be in an unfamiliar language, incomplete, with complex keys, highly technical descriptions, and inadequate illustrations. If, despite all odds, the user obtains a tentative identification, definitive confirmation against reference collections may be virtually impossible.

Yet the countries that have the greatest difficulties identifying their plants are often those with the highest species diversity and thus the greatest need. It is vitally important for these countries' future – and that of global biodiversity – that their biota be adequately identified, studied, protected and managed. Thus we must develop mechanisms that allow reasonable information control by custodians, yet at the same time promote maximum use of that information by those who need it most.

Conversely, those who are creating information systems must plan carefully for information dissemination as part of the process of implementing an information strategy. Whether provided through direct access, a third party, or distributed paper or electronic products, the information must be accessible, relevant to users, and understandable. Potential users must also know that the information is available.

Current methods of information dissemination take a wide variety of forms, which are summarized in Table 9.4-2. This variety is expected to increase in future.

9.4.3.1 Printed media

In the form of reports, tables, graphs, images and maps, printed materials will remain the major form of information communication for many years to come. Reproduction in large quantities through printing presses is relatively straightforward, though expensive (particularly for colour). Distribution procedures for books and journals are well developed. Cost can be an issue in many countries, particularly where currency exchange is difficult.

Printed material can be viewed almost anywhere without additional aids. Further analysis, through overlay of printed maps or extraction of numeric data from tables, is possible, though awkward and time consuming. Neither animation nor audio is, of course, possible. It is probably true to say that, despite the advent of computers and electronic networks, there is more paper circulating at present than at

Table 9.4-2: Characteristics of media for the distribution of data.

Medium	Application	Advantage	Disadvantage	Costs
Paper	Presentation of condensed data	No special tools needed	Restricted size of data set	Low for text, high for pictures
Disks	Presentation of condensed data	Easy to manipulate	Restricted size of data set, computer required	Low for disk, high for computer
CD-ROM	Customized access to large data sets	Interactive, easy to use	Computer required	Low for disk, high for computer
Electronic	On-line retrieval of frequently updated data	Huge volume, networkable	Searching can be complex; connection required	High for computer and network connection

any time in the past. Recent developments in other media are, however, making inroads on more traditional products as well as creating new market opportunities. One reason is that publication through print takes months or years, whereas electronic distribution can take place within hours.

9.4.3.2 Electronic media

Computer-based media are excellent for distributing large volumes of information in compact forms. These include storage media such as floppy disk, optical disk, CD-ROM and data cartridge. A major advantage is that very large volumes of data, in a wide variety of formats, can be stored on quite small objects. Laser videodisks, for example, can hold photographs of herbarium specimens, 35 mm slides of plants in their habitats, printed illustrations (including close-up illustrations of diagnostic features), distribution maps and other information. Storage capacities are so large that storage of many illustrations per species is feasible.

An advantage of CD-ROMs is that they are cheaper to produce than printed works, especially when many full-colour pictures are needed. Updates can also be readily produced and distributed. Easy distribution, with minimal mailing costs, ensures wide access. On the other hand, technologies such as computers and CD-ROM drives are required to access the information. Recent examples of ‘publications’ using these technologies include ‘*Beetle Larvae of the World*’ by CSIRO in Australia. Another development in this area is the Expert Centre for Taxonomic Identification (ETI) in the Netherlands and their use of multimedia technology and innovative tools for identification and database storage in a custom-built program distributed on CD-ROM.

9.4.3.3 Networks

Information must be available not only to human eyes but also to computer-based tools used to analyse large complex data sets.

Systems such as Gopher and World Wide Web servers (see Table 9.3-1) accomplish two major objectives: first, they serve as ways of displaying significant documents, descriptions of current activities, organizational business, etc., and second, they serve as links to biodiversity and other information. Much of what is currently available on the network can basically be described as electronic copies of printed media. In some cases, such as the newly establishing ‘electronic journals’ (e.g. *Electronic Green Journal*), only the electronic form actually exists and a paper version is dispensed with completely. Among the many advantages of such publications is that, instead of needing to incorporate illustrations and other material from previous work, with all the administrative and technical overhead involved, links can be made directly, within the paper, to other ‘published’ sources. As navigation aids, these sources can provide a cohesive focal point for biodiversity information managers and analysts, helping to form a community that places people at the threshold of the information they need.

9.4.3.4 Microfilm and microfiche

In the past 25 years or so microform has been one of the main ways for libraries and organizations to store large quantities of documents. The main advantages of microform storage are:

- small space requirements;

- relatively cheap production and distribution of microform and microfiche, in particular; and
- recognized international standards which assure the quality and thus the longevity of the medium under the appropriate storage conditions.

The main disadvantage with the medium is user aversion. A microfiche reader is an essential tool to permit the information on the microform to be read as it cannot be read with the naked eye. Reader aversion to microforms is due to difficulties experienced in finding the correct pages as serial searching is required with microfilm or the seeming 'jumping around' in the case of microfiche. Thus, although not essential, a microform reader which can provide prints is highly desirable. Microforms are principally used for distribution of reports and learned journals.

9.4.3.5 Distribution channels

The distribution of the various kinds of information packages depends on the kind of information carrier. There are three main categories of distribution channels: printed material, computer media, and electronic network services.

The advantage of printed media, such as books, journals, reports and maps, is that they are portable and may be used anywhere at any time convenient to the user. This implies that there are mechanisms (advertising, product reviews, etc.) to inform the user of the availability of the information, how to order it and then to distribute it. This, traditionally the domain of professional publishers and retailers, has a long history of working reasonably well, but there is no guarantee that the potential market is fully supplied.

More recently, data and information have been distributed on electronic media such as diskettes, CD-ROMs, cartridge tapes and videodisk. Provided the technology to access these data is available – at a minimum a personal computer – this is also a reasonably flexible and comparatively low technology distribution channel.

Electronic network services promote the on-line accessibility of the very latest information. It is generally assumed that there is no widely available information that is more up-to-date. Access to this information, however, is conditional on establishing and maintaining some form of physical connection to a network node. In addition, developing and maintaining these network services requires technology and resources that are sometimes not available in developing countries.

9.4.4 Issues in electronic publishing

The advent of the World Wide Web makes network publishing a reality. The Web deals with 'hypermedia' (hypertext + multimedia). Documents are formatted, with embedded figures, as with traditional paper publications.

However, they have the added power of multimedia and of hypertext links to items anywhere in the world. This information can be text, images, animation, sound and data (Green and Croft 1994). For example, a reference in a document to the Convention on Biodiversity can be a direct link to the text of that document, located in a computer somewhere else on the network.

A major advantage of network publication is that material can be updated continuously and be instantly available to users in a transparent fashion. The current status can be assured through direct links or by 'mirroring', i.e. automatically downloading copies at frequent intervals (Green and Croft 1994).

The sheer variety of forms in which information can be transmitted around networks leads to challenges in quality control and appropriate attribution of credit for intellectual contributions. In the case of printed journals, well-established procedures of peer review are in place to try to maintain uniform high quality. If a contribution fails to meet appropriate standards, it is simply not published, at least until modified. Frustrated authors do have alternative avenues: non-refereed journals, private publishing and personal circulation, but these contributions are generally discounted by their peer community. Career advancement is often based on assessments of contributions to the peer-reviewed literature and citations of those contributions.

With the advent of World Wide Web and other network servers, anyone with a computer and a connection can make a contribution. Many of these contributions are proving invaluable in many fields, and a number of individuals are building well-deserved global reputations. There are so far, however, no mechanisms to authenticate or provide quality assessments of material thus made available. More formal recognition for contributions to network resources and infrastructure, particularly with respect to career advancement, is in very early stages of development.

9.5 Sources of biodiversity information

9.5.0 Introduction

In recent years there has been an explosion of effort by the world's communities, scientists, industries, governments and policy-makers to better understand, use and conserve biological diversity. However, much of the information on biodiversity remains in the domain of scientists. For example, much statistical data on species and habitats exists, yet it is largely scattered through research institutes, universities, zoos and botanical gardens, and not accessible in a form useful for policy-makers (see Section 8.4).

At the same time there have been significant shifts in environmental management policies, and parallel shifts in the requirement for environmental information. While much biodiversity information generated in the past was

descriptive, recent efforts in compiling biodiversity information also seek to address the conservation and sustainable use of biodiversity, integrating biological data with the ecological, social, economic and policy dimensions of biodiversity management.

For many countries, much of the existing information about plant and animal species is held in collections or databases located in other nations. If that information is already computerized, it is neither particularly difficult nor expensive to make copies available to the source country's research and management agencies – provided one can find it. A problem arises, however, when information is not available in electronic form and, particularly, when relevant plant and animal specimens are scattered throughout large collections around the world. Locating these specimens and computerizing the data that accompanies them is extremely time-consuming and expensive. In such situations, it is important to establish, as rapidly as possible, strategies and resources for obtaining the information needed.

As governments must now take action to ensure the conservation and sustainable use of biodiversity, policy-makers need significantly improved access to this information. At the same time, a broad range of other constituents need information about the distribution, health and policy relevance of the ecosystems in which they live, and of the elements that make up those systems. This chapter addresses some of the mechanisms by which this information can be located and retrieved (see also Section 8.4).

9.5.1 Libraries, bibliographies and bibliographic databases

Libraries are established with the express purpose of being information centres, and mechanisms and agreements are in place which facilitate the exchange of information on collections, and the searching for, and loan of, material. This is supported by the use of catalogues and indexes, and by bibliographies, bibliographic databases and abstracting services.

9.5.1.1 Libraries

When reviewing available sources of information, careful attention should be paid to *national collections* of both published and unpublished literature. National libraries are often the depository for copies of all works published in that country. In addition, some are charged with collecting all material published by a national whenever the work is published, and/or attempting to acquire all material published about the country.

Another key source will be the libraries of internationally operating organizations carrying out work relevant to biodiversity and its management. Many of these libraries are thematic, drawing material from sources right around the world; others are regional in their coverage. See 9.5.5 and Table 9.5-1.

Other types of organizations that may hold relevant collections of literature include:

Table 9.5-1: Selected libraries of international significance.

1. Asian Institute of Technology	
2. BirdLife International	
3. Consultative Group on International Agricultural Research	
– Centre for International Forestry Research	
– International Centre for Tropical Agriculture	
– International Maize and Wheat Improvement Centre	
– International Potato Centre	
– International Plant Genetic Resources Institute	
– International Laboratory for Research on Animal Diseases	
– International Livestock Centre for Africa	
4. Institute Français de Recherche Scientifique pour le Développement en Coopération	
5. International Centre for Integrated Mountain Development	
6. International Centre for Living Aquatic Resources Management	
7. International Development Research Council	
8. International Waterfowl and Wetlands Research Bureau	
9. National Library of Agriculture (USA)	
10. The Natural History Museum (UK)	
11. Royal Botanic Gardens, Kew and Edinburgh (UK)	
12. Smithsonian Institution (USA and Panama)	
13. United Nations organizations	
14. IUCN – The World Conservation Union	
• government departments (such as forestry, agriculture, fisheries, environment, natural resources and tourism);	
• universities and other seats of higher learning;	
• research institutes, museums and botanic gardens;	
• learned societies and professional associations; and	
• non-government organizations.	
Libraries the world over are experiencing financial constraints, and these pressures tend to focus activities such as collection building to meet the needs of the primary user	

Box 9.5-1: On-line reference databases services.

There are a number of good on-line information sources available today. By far the largest commercial system available is DIALOG, which comprises more than 450 databases containing more than 330 million articles, abstracts and citations covering a variety of topics, with particular emphasis on news, business, science and technology. For example, DIALOG offers:

- the complete text of articles from more than 2500 journals, magazines and newsletters
- the complete text of more than 60 leading US and international newspapers, plus wire service stories from Knight-Ridder/Tribune Business News, PR Newswire, Business Wire, and Reuters;
- references to and abstracts of articles from more than 100 000 international publications on science and technology, social sciences and humanities;
- details on more than 15 million patents from 46 patent-issuing authorities worldwide, and
- data on more than 10 million chemical substances.

group, and foster networking and co-operation between libraries. In this context some libraries or parts of their collections are now referred to as ‘information centres’, ‘resource centres’ or ‘documentation centres’ where the emphasis is placed more on the information delivery than simply organizing and storing information.

9.5.1.2 Bibliography

Material relating to biodiversity can be found not only in the literature of the biological sciences and the related applied sciences (such as forestry, fisheries, agriculture, wildlife management and conservation biology), but also in literature related to economics, social sciences and even legislation. However, the terms ‘biodiversity’ and ‘biological diversity’ are relatively recent, and other concepts and key words also need to be used in searching for relevant literature.

Perhaps more than in most sciences, there is also a substantial body of knowledge and experience to be found in the ‘grey’ literature, for example, reports from consultancy groups, field workers, research workers and non-government organizations, and reports to government departments. Most of this knowledge is never formally published, and is often extremely difficult to trace, and thus obtain copies. Often the grey literature may be

1. Abstracts on Tropical Agriculture (ORBIT)
2. Agricola (DIMDI, Data-Star/Dialog)
3. AGRIS International (Data-Star/Dialog, DIMDI, ESA-IRS)
4. Aquatic Sciences and Fisheries (Data-Star/Dialog, DIMDI)
5. Biological and Agricultural Index (BRS)
6. BIOSIS Previews (Data-Star/Dialog, DIMDI)
7. CAB Abstracts (Data-Star/Dialog, CAN/OLE, DIMDI)
8. GEOBASE (Data-Star/Dialog, ESA-IRS)
9. Life Sciences Collection (Data-Star/Dialog, STN International)
10. Microbial Information Network Europe (DIMDI, Deutsche Sammlung von Mikroorganismen und Zellkulturen GmbH)
11. Oceanic Abstracts (Data-Star/Dialog, STN, ESA-IRS)
12. Remote Sensing On-Line Retrieval Systems (ORBIT, ESA-IRS)
13. SciSearch (Data-Star/Dialog, DIMDI)
14. UBIB UNESCO Bibliography (ECHO)
15. Zoological Record On-Line (Data-Star/Dialog)

Note that a number of these are also available in published format.

prepared for a very limited audience and it may never be intended to be publically available. As a result, it can often be found only by talking to workers in the field, contacting relevant organizations, or in the reference lists of other publications.

9.5.1.3 Bibliographic databases

There are a number of specialist bibliographic databases on relevant subjects, some of which are available on-line (see Box 9.5-1). No single service covers all aspects of the subject and thus there is significant overlap between them. Emerging disciplines, such as economic valuation of biological resources, do not always sit comfortably in the

coverage of scientific databases, and are not adequately covered at present. See Table 9.5-2 for examples of available services.

9.5.1.4 Periodicals

The 32nd edition of *Ulrich’s International Periodicals Directory 1993–94* (Bowker 1993) lists approximately 250 serial publications under the heading ‘conservation’ (although not all cover biodiversity conservation), and there are several other headings relevant to biodiversity. Further, this list selects only key learned journals. Many organizations produce newsletters with the aims of disseminating information to particular interest groups. For example, in the Asia region FAO produces *Tigerpaper* with information about conservation projects in the region. These can best be traced through references in the literature, knowledgeable individuals, or information centres familiar with the regions or topics concerned.

9.5.2 National biodiversity information centres

In a wide range of countries, the need to improve information management has already been appreciated, and databases and/or information centres have been established. Some of these centres are autonomous (such as the Conservation Data Centre of Bolivia), some are to be found within non government organizations (such as the Costa Rican Conservation Data Centre at the Fundación Neotropica), others are located within university departments (such as the database on species, habitats and protected areas at Mahidol University in Thailand), and others are managed under government auspices (such as the database on India’s National Parks and Wildlife Sanctuaries managed by the Indian Institute of Public Administration). For another example see Box 9.5-2.

The aims and objectives of the centres range widely, with some centres concentrating on the distribution of species (such as the UK Biological Records Centre), while others concentrate on aspects of management and the impact of humans (such as the Indian database already mentioned). Working practices will also vary widely. Some, such as the Conservation Data Centres in Latin America have all the data collected on one site, while others, such as the Australian Environmental Resources Information Network are based on a distributed network approach (see Box 9.5-3). Yet whatever the objectives or approach, each of these information centres will have a significant body of information on the country in question, and access to an even greater body of information through its contacts both within the country and elsewhere.

In order to effectively implement the Convention on Biological Diversity, and in particular Article 6 which deals with the development of ‘national strategies plans

Box 9.5-2: Indira Gandhi Conservation Monitoring Centre, India.

The Indira Gandhi Conservation Monitoring Centre (IGCMC) has been established by WWF India as a major national facility, with the full support of the Government of India, with a view to providing information support to government and non-government programmes for environmental conservation in the country. The objectives of IGCMC are to:

- maintain information on India’s natural resources, especially its biological diversity (including indigenous plant and animal species, habitats of conservation importance, national parks and protected areas, and the trade in threatened species of wild flora and fauna);
- gather, store, retrieve and disseminate such information through a modern information management system;
- form collaborative links with other relevant natural resource organizations within India, including government research and survey institutions, universities and non-government organizations; and
- form collaborative links with other relevant organizations outside India.

and programmes for conservation and sustainable use of biological diversity’, it is essential that there is a good information base from which to work. In order to assist in the implementation of this and other articles, UNEP is currently managing a project, supported by the Global Environment Facility, which will assist a number of countries in the development of their information management capability. Part of this project involves the preparation, by WCMC of a range of materials which will provide guidance and assistance to countries in the development of improved information management at the national level. In particular, the project is developing guidelines and standards for biodiversity data management, information on appropriate technologies, and know-how for the management and application of data and methods of accessing sources of biodiversity information and technology.

9.5.3 National biodiversity assessments

Heightened awareness of threats to biodiversity over recent decades has brought about increased efforts to take stock of what is at threat. Series of inventories of biodiversity and

Box 9.5-3: Environmental Resources Information Network, Australia.

ERIN was established in 1989 by the Australian Government and is part of the Federal Department of the Environment, Sport and Territories. ERIN is a national facility, with a goal to provide environmental information required for planning and decision-making. The information covers many aspects of the environment of the continent of Australia and adjacent maritime areas. It is drawn from many sources and includes maps, species distributions, documents and satellite imagery. Building such a broad information base has involved close and continuing co-operation and collaboration with research, government, industry and other sectors of the community.

The ERIN information bases were designed to answer questions crucial to the management and conservation of the Australian environment. These include:

- What is found in a particular region?
- Where is something (such as a type of management zone, an environmental resource or a rare species)?
- What kinds of environments exist and where are they found?
- How are these environments being managed?
- Is the environment changing and by how much?

and, the most difficult question of all:

- What will happen if ...?

The answers to these questions are urgently required by government, industry, researchers and community groups. Information is needed to contribute to the development of environmental policies and the assessment of development proposals. There is also a growing requirement to provide environmental information for education and regional land management purposes.

assessments of its status have been carried out in many countries and regions by international organizations, foreign assistance donors, international conservation groups, and local governments and NGOs (WRI/IUCN/UNEP 1992). These efforts to obtain an understanding of global and national biodiversity have grown to constitute a large yet generally uncoordinated source of biological information.

Nearly every country in the world has produced at least one national environment report (WRI/IIED/IUCN 1992), although the content of these reports varies widely from country to country. Some national reports touch on all aspects of a country's environment, providing only an overview of the environmental problems. Other more specialized environmental studies may cover particular sectors (such as forestry or biodiversity), looking in more depth into their status and the problems they face.

As the need for policy-relevant information has grown, these assessments have begun to take a broader approach which includes the integration of biological data with a wide range of other environmental information, coupled with policy analysis, the identification of policy options, and possibly a strategy or action plan with programme initiatives and implementation and monitoring procedures.

In recent years, several international programmes have provided consistent reporting on the state of countries' environments, with specific sector studies on forestry and biodiversity (see Table 9.5-3).

9.5.3.1 Country environmental profiles

These are broad introductions to the environmental issues within a country, offering basic references on the state of the environment, as well as indicating where urgent problems may lie and where future resources should be invested. They can help policy-makers identify opportunities for improving the environment and set priorities (Parker and Hope 1992).

Most of the programmes initiated to produce such profiles have been carried out by donor country governments to strengthen environmental considerations in their development assistance programmes (WRI/IIED/IUCN 1993). Some profiles are simply environmental synopses produced as desk studies which draw on published sources of information, others are considerably more consultative in their approach, involving extensive dialogue, research and review phases, and reaching consensus on an 'action agenda' to deal with the priority issues (WRI/IIED/IUCN 1993).

Generally, country profiles or national environmental reports include an analysis and description of the most important environmental issues, and an overview of the monitoring, research and administrative capacity of the countries to address environmental problems. However, as environmental profiles are usually broad environmental synopses, they are generally of limited use to decision-makers in terms of biodiversity. As the need for more information on biodiversity has grown, so too have programme efforts to provide such information.

9.5.3.2 Biodiversity assessments

Before policies, strategies and action plans could be developed to address biodiversity conservation, it became

obvious that a baseline understanding of the extent and magnitude of a country’s biota was needed. Development assistance agencies and international organizations took the lead in initiating national reports on the state of biodiversity. Their aim was to feed the ever growing awareness of, and responsibility for addressing, the rapid depletion of the world’s biological diversity.

National biodiversity assessments generally contain information on the laws and institutions affecting biological resources; the status and protection of endangered species; conservation efforts both within and outside protected areas; impacts of development projects; conservation facilities (such as seed banks, zoos, botanical gardens and sometimes micro-organism genetic resource collections); conservation of economically important species; major issues in biological diversity conservation; and recommendations and proposed activities (WRI/IIED/IUCN 1993).

Some biodiversity assessments have also been produced by agencies outside the country concerned, although usually for briefing purposes rather than as a definitive assessment. An example would be the profiles compiled by the World Conservation Monitoring Centre (WCMC), which can serve as easily accessible reference summaries (WRI/IIED/IUCN 1993).

9.5.3.3 UNEP country studies programme

The principal goal of this programme is to assist countries in assessing the status and value of their biological resources, and to show how countries can deploy this information as an input to the national biodiversity planning process required under the Convention on Biological Diversity. The revised guidelines (UNEP 1993) focus on the compilation of biological and economic data to reinforce the biodiversity planning process within countries, rather than on quantifying the unmet financial needs of nations to implement the articles of the Convention (which had been the primary orientation of the first tranche of studies).

Components of the revised Country Studies on biodiversity include (UNEP 1993):

- identification of components of biodiversity that are important for its conservation and sustainable use;
- collection and evaluation of data needed for the effective monitoring of the components of biodiversity;
- identification of processes and activities that threaten biodiversity;
- evaluation of the potential economic implications of the conservation and sustainable use of biological resources;

Table 9.5-3: Examples of organizations that have supported development of country environmental profiles and biodiversity assessments.

International organizations	
1.	IUCN – The World Conservation Union – Conservation of Forest Ecosystem Studies and national conservation strategies.
2.	United Nations Conference on Environment and Development (UNCED) – encouraged the preparation of national reports (the development of many of the reports supported by UNEP).
3.	United Nations Environment Programme (UNEP) – State of the Environments reports, and biodiversity country studies.
4.	World Bank – Environmental issues papers (EIP) and national environmental action plans (NEAP).
5.	World Conservation Monitoring Centre (WCMC) – national biodiversity profiles, and support to the UNEP biodiversity country studies programme.
6.	Conservation International (CI) – promotion of Workshops for definition of Biodiversity Priority Areas at national and regional levels.

Compiled from WRI/IIED/IUCN (1992), and Olivieri (1995).	
•	determination of the economic values of biological and genetic resources, and
•	assessment of priority actions for the conservation and sustainable use of biodiversity.

The Country Studies are a potentially useful step mechanism for integrating biological data with assessment of its value and the degree of threat to its integrity, linking this with the necessary policy-relevant information. The result will assist policy-makers in developing national strategies and action plans, and other programmes to better conserve their biodiversity. To date, 40 countries have either completed, are in the process of, or have expressed interest in producing a Country Study on Biodiversity.

9.5.4 Global and regional assessments

In addition to the various nationally focused efforts to report on biodiversity, there are numerous studies that present information on the status and trends of the global environment in general, and sectoral or thematic topics in particular. While these reports are not intended to be used for national environmental planning efforts, they often serve to inform policy-makers about the global trends and conditions that are relevant to the national situation. These reports have been instrumental in alerting the international community to global problems in the environment which ultimately necessitate concerted mitigation efforts at the national scale.

9.5.4.1 Global environment reports

Most of the globally focused reports contain relatively up-to-date analyses of environment and development issues. They also contain sets of indicators and data tables that can be used directly or help the user locate more information. Some, such as the World Resources Report and the World Development Report, provide statistical tables and time series on diskette (Table 9.5-4).

9.5.4.2 Thematic reviews

More frequent, and perhaps more useful than global reviews, are those that take particular themes (such as a particular habitat or species group) and review the status and distribution of that feature, and often the actions that need to be taken for its improved conservation or management. Because there are substantial numbers of such reviews, rather than try to list them in their entirety it seems sensible to provide some examples of several different types of review.

- Different aspects of conservation legislation have been reviewed by a number of organizations and individuals. The results of much of this experience are summarized by de Klemm (1990) and de Klemm and Shine (1993).
- Tropical forest atlases have been produced for both the African and Southeast Asian regions, and will shortly be available for Latin America. These are compiled by WCMC and IUCN, again working in close collaboration with national and international agencies (Sayer *et al.* 1991, 1992).
- More in-depth studies of particular species groups, such as the study of forest bird communities in Hawaii (Scott *et al.* 1986), or on the ecology and conservation of grassland birds (Goriup 1988) have been published by various organizations.

9.5.4.3 Regional assessments

While national assessments and profiles can help to address priorities and needs *within* a country, regional assessments can help to place those priorities and needs in a wider context. For this reason a number of international and intergovernmental organizations have promoted the development of regional reviews or assessments covering, at one time or another, most regions of the world. There is a wide range of such reviews, so the following examples are necessarily only representative.

- Workshop 90, held in Manaus, Brazil, brought together a hundred scientists from 15 countries, all specialists on the biodiversity of the Amazon Basin. The workshop produced a map of priority areas representing the consensus of the scientific community, and had an important impact on the region. This approach of combining information compilation and synthesis with an expert workshop with broad participation, using a GIS as a tool for unifying and representing priorities, has been developed further since then and has been applied to other regions and countries including Papua New Guinea, the Atlantic Forest of Brazil and Madagascar.
- In the mid-1980s, UNEP commissioned IUCN to prepare protected area systems reviews covering both tropical Africa and Southeast Asia. The two reports (MacKinnon and MacKinnon 1987a, b), were based on detailed studies by consultants which involved regional meetings and travel to the countries covered, as well as using the database already compiled by IUCN/WCMC. Each study aimed to identify where the shortcomings in existing protected area systems were, and resulted in proposed action.
- In order to develop a sound basis for its policy on biodiversity conservation, USAID sponsored a

- The International Council for Bird Preservation (now BirdLife International) has reviewed the distributions of all bird species occupying an area of less than 50 000 km², identifying a series of 'endemic bird areas' where two or more restricted-range species are to be found (Bibby *et al.* 1992).
- Directories of wetlands have been compiled for various parts of the world by IWRB and IUCN working in close collaboration with a number of national and international organizations. Examples include Scott and Carbonell (1986), Scott (1988), Hughes and Hughes (1992) and Scott (1993).

process to define priority areas for biodiversity conservation within the Latin American and Caribbean Region. After compiling and analysing available information it culminated in a one-week workshop of regional experts during September 1994. The results included an assessment of the level of knowledge of biodiversity, and areas of high biological importance, and an analysis of the level of threat to biodiversity. The process was carried out by a consortium of institutions including Conservation International, The Nature Conservancy, World Resources Institute, World Wide Fund-US, and the Wildlife Conservation Society, co-ordinated by the Biodiversity Support Program.

- Information can also be compiled, and then used in conjunction with our understanding of the implications of different policy options, to assess the potential impact of those policies. See, for example, Bischoff and Jongman (1993) which looks at the potential impact of land-use choices in Europe.

9.5.5 Global, regional and thematic information centres

A major source of information can be those internationally operating organizations which, as part of their operations, either compile or improve access to information on a wide range of issues, and from a wide range of sources. These may be international organizations (such as the World Conservation Monitoring Centre), regional organizations (such as the European Environment Agency) or thematic in orientation (such as BirdLife International). Their primary orientation may be towards information (such as UNEP-INFOTERRA) or towards research (such as the CGIAR centres). Some selected centres are listed in Box 9.5-4.

Improvements in computer communications have allowed the rapid development of information services that can be accessed by substantially more people than ever before. Many of these international organizations listed in Box 9.5-4 have Internet facilities, but these do not yet provide access to most of the information they have available. Such capacities will develop over the years, in part driven by development of the 'Clearing

Box 9.5-4: Selected international information centres.

BirdLife International: Birdlife International is a federation of 360 member organizations in 100 countries. It is dedicated to saving the world's birds and their habitats. It conducts research into the status of and threats to birds throughout the world; works to protect endangered birds and promote public awareness of their ecological importance and lobbies policy-makers on issues relating to bird conservation. Birdlife International publishes various technical publications and monographs.

CAB International: CAB International is an intergovernmental organization which provides research information, and scientific and development services for agriculture, forestry and related disciplines throughout the world. It has the world's largest bibliographic database (CAB Abstracts) of relevant research and development publications. There are four constituent institutions: International Institute of Entomology; International Mycology Institute; International Institute of Biological Control; International Institute of Parasitology.

Consultative Group on International Agricultural Research: CGIAR consists of a consortium of donor countries, foundations and development banks, jointly sponsored by the World Bank, FAO and UNDP. Its establishment was motivated by international concern over the problems of genetic erosion in cultivated species and the loss of related wild species of flora. At present there are 13 International Agricultural Research Centres supported by the CGIAR. Most of these centres have specific responsibilities in crop varietal development and germplasm conservation. A few of these centres also serve as an international base for specific crops and actively collect on a world-wide basis. The collection efforts of the CGIAR network were initially focused on crop plants and were based on the economic importance of the crop, the quality of existing collections and the degree of threat to the crop.

European Environment Agency: EEA was conceived as a co-ordinating unit for a large decentralized network, providing the European Union and its member states with objective and reliable information and assessment on the state of the environment in Europe. In the first years of its operation, emphasis will be placed on providing information that can be used directly in environmental policy implementation. Such areas include: air quality and atmospheric emissions; water quality, pollutants and water resources; the state of soil, flora, fauna and biotopes; land use and natural resources; waste management; noise emissions; environmentally hazardous chemical substances; coastal protection. Various European organizations have already been appointed as 'topic centres' to coordinate information management in several of these sectors.

Food and Agriculture Organization of the United Nations: FAO carries a major programme for the agricultural community on behalf of governments and development agencies; collects, analyses and disseminates information; advises governments on policy planning; and provides opportunities for governments to meet and discuss food and agriculture problems. The major FAO units concerned with environmental and natural resource problems and issues are: the Interdepartmental Working Group on Environment and Sustainable Development; Forestry Department; Fisheries Department; Agriculture Department; and the regional commissions and technical committees.

International Council of Scientific Unions: CODATA is a scientific committee of ICSU, established to address data quality and utilization on an international level. CODATA was given several general objectives: to improve data quality and accessibility, as well as the collection, management and analysis methodology; to facilitate international co-operation among those collecting, managing and using data; and to promote an increased awareness in the scientific and technical community of the importance of these activities.

International Centre for Living Aquatic Resources Management: ICLARM conducts and fosters research and training in aquaculture, fisheries management and coastal area management. The Centre works to resolve critical technical and socio-ecological constraints to increased production, improved resource management, and equitable distribution of benefits. ICLARM publishes *Naga*, *The ICLARM Quarterly*; bibliographies; educational materials; technical reports; and conference proceedings.

International Institute for Applied Systems Analysis: IIASA's research efforts are primarily related to the development and use of scenarios and computer models. These activities include: environment; systems and decision sciences; technology, economy and society; and population. Data and information management are an integral part of model and scenario development, which are primarily in the areas of biosphere dynamics, trans-boundary air pollution, water resources, environmental monitoring and climate change.

Box 9.5-4 cont.

International Plant Genetic Resources Institute: IPGRI (formerly IBPGR) is an autonomous international scientific organization operating under the aegis of CGIAR. Its mandate is to advance the conservation and use of plant genetic resources for the benefit of present and future generations. IPGRI is expanding its information service to meet the needs of the plant genetic resources community. Existing services and databases held by other institutions already cater for many of these needs. Wherever appropriate, IPGRI refers users to such sources.

IUCN – The World Conservation Union: IUCN's mission is to provide knowledge and leadership for the sustainable use of natural resources. It provides leadership that can guide governments, aid agencies, non-governmental organizations and local communities investigating the causes of environmental change and degradation in different places, assessing the problems, and determining options for solutions. IUCN publishes authoritative reviews on conservation policy and on the status and urgent conservation needs of flora and fauna. It also publishes directories, handbooks, guides, reports and guideline documents on biodiversity conservation. IUCN's various expert groups include the Commission on National Parks and Protected Areas, the Environmental Law Centre and the Species Survival Commission.

UNEP Global Resource Information Database: GRID, part of the Global Environment Monitoring System (GEMS) network, aims to collect and disseminate the most advanced information available on the state of natural resources world-wide. In order to better collect, manage and disseminate data sets and other information, GRID has established a series of *nodes*. At the moment there are four nodes: Nairobi, Geneva, Bangkok and Arendal, Norway. The information GRID holds consists of processed geo-referenced data sets drawn from various sources, including the GEMS network.

UNEP International Environmental Information System: INFOTERRA was established by UNEP to identify and aid in the exchange of sources of environmental information and expertise. It was established as a decentralized world-wide network of information storage and dissemination facilities. These are primarily independent National Focal Centres (NFCs) whose activities are co-ordinated by the INFOTERRA Programme Activity Centre. Information is made readily available through a variety of means, including regular publications such as *International Directory of Sources* and the *World Directory of Environmental Expertise*.

United Nations Educational, Scientific and Cultural Organization: UNESCO was established 'for the purpose of advancing, through the educational, scientific and cultural relations of the peoples of the world, the objectives of international peace and the common welfare of mankind'. UNESCO has set up various forms of inter-governmental co-operation concerned with the environmental sciences and research on natural resources, with key programmes including the Man and the Biosphere Programme, the International Network of Biosphere Reserves and the World Heritage Convention.

United Nations Statistical Division: UNSTAT (formerly the United Nations Statistical Office) concentrates on developing economic methodologies. Two current projects involve the development of indicators for sustainable development and environmental accounting.

World Conservation Monitoring Centre (WCMC): WCMC provides information services to support the conservation and sustainable use of biological diversity, and also assists others in the development of their own information management systems. WCMC has particular experience in the management of information related to species, habitats, protected areas, and financial investment in biodiversity conservation.

House Mechanism' anticipated by the Convention on Biological Diversity (Box 9.5-5).

9.5.6 On-line sources of information

Organizations throughout the world are discovering the new opportunities provided by improved information technology and the development of communications networks. The use of discussion lists, on-line databases, virtual libraries and Special Interest Networks is

expanding rapidly. Examples of such developments in the field of biodiversity are the Australian Environmental Resources Information Network (see Box 9.5-3) (<http://kaos.erin.gov.au/erin.html>), the Biodiversity and Ecosystems Network (BENE) in the USA (<http://straylight.tamu.edu/bene/bene.html>), and the Base de Dados Tropical (BDT) in Brazil (<http://www.bdt.org.br>).

The growth of this medium is so rapid that it is difficult to keep abreast of developments, but there are

Box 9.5-5: Clearing house mechanism.

Article 18(3) of the Convention on Biological Diversity requires the establishment of *a clearing house mechanism to promote and facilitate technical and scientific co-operation*. The Interim Secretariat to the Convention has convened meetings to discuss the proposed mechanism, and to explore means by which the mechanism can provide access to information services, technical assistance and advice.

The principles for a successful co-operative clearing house are stated in the recommendations of the second session of the Open-ended Intergovernmental Meeting of Scientific Experts on Biological Diversity (UNEP/CBD/IC/2/11), which can be summarized as:

- an openly accessible electronic data network;
- a decentralized network of national and regional centres with central co-ordination;
- based as far as possible on existing institutions;
- based as far as possible on existing databases, information services, and networking services;
- driven by the needs of contracting parties; and
- small in the initial phase but with the capacity to be developed further.

At present a key thrust of discussion is towards mechanisms for facilitating information exchange, which must be based on a strategy which:

- reviews information needs for implementation of the Convention;
- identifies where those needs are already fulfilled, and where the gaps are;
- ensures effective dissemination of information from the existing information sources;
- ensures the co-ordinated use of existing information services; and
- develops a programme for meeting information needs not already satisfied by existing sources and services.

Information services that meet some of the needs of contracting parties either already exist, or could easily be developed from existing information sources. Initial implementation of the Clearing House Mechanism will need to recognize and use these facilities to improve the information available to contracting parties, both through computer networks and through more traditional means of information dissemination.

mechanisms for keeping up to date, ranging from mailing lists and newsgroups to metadatabases, virtual libraries and 'Special Interest Networks'. The Internet Services List by Scott Yanoff is a good overview list of Internet resources, and is regularly updated (<http://www.uwm.edu/Mirror/inet.services.html>). The InterNIC Directory and Database Services (<http://www.internic.net/ds/dspg01.html>) is also a good source for general Internet resources.

Without tools and methodologies for gathering, evaluating, managing and presenting the wealth of information through on-line means, most of this knowledge could be lost. New tools and different information networks and organizations are filling this niche, including Metadatabases (9.5.6.1), Virtual Libraries (9.5.6.2) and Special Interest Networks (9.5.6.3). However, these can be supplemented by a growing number of 'search engines' which locate information sources based on words provided by the searcher.

9.5.6.1 Metadatabases

Metadatabases, as defined earlier, provide information on what information is available where to a diverse set of users, using a structured description of the available data sets. Good examples of metadatabases are UNEP's GRID Database (<http://www.inpe.br/grid/home>), the Federal Geographic Data Committee (<http://fgdc.er.usgs.gov/>) and CIESIN (<http://www.ciesin.org/>).

The Global Resource Information Database (GRID) is a system of co-operating centres within the United Nations Environment Programme (UNEP) dedicated to making environmental information more readily accessible to environmental analysts as well as international and national decision-makers. Its mission is to provide timely and reliable geo-referenced environmental information. Besides acquiring and disseminating integrated, spatially-referenced environmental data, GRID provides decision-support services to environmental analysts and international and

national decision makers, and fosters the use of geographic information systems (GIS) and satellite image processing (IP) as tools for environmental analysis.

The US National Spatial Data Infrastructure (NSDI) encompasses policies, standards and procedures for organizations to co-operatively produce and share geospatial data. The US Federal Geographic Data Committee (FGDC) has assumed leadership in the evolution of the NSDI in co-operation with state and local governments, academia and the private sector. CIESIN, the Consortium for International Earth Science Information Network, specializes in the access and integration of physical, natural and socioeconomic information across scientific disciplines. Other major programmes with international data access roles include the US National Aeronautics and Space Administration (NASA) Global Change Master Directory and, in the UK, the Global Environmental Network for Information Exchange (GENIE). A number of major metadatabases are described in Table 9.5-5.

Many other agencies have set up co-ordinating centres providing links to more specialized information sources elsewhere. Examples on the World Wide Web include plant fossil records (<http://sunrae.uel.ac.uk/palaeo/pfr2/pfr.html>) and plant viruses (<http://life.anu.edu.au/.viruses/virus.html>). At the genetic level, Genbank – the database of all published nucleic acid sequences – is accessible through the Internet (fly.bio.indiana.edu/11/Genbank-Sequences), and entries can be found and retrieved by Accession Number, Description, Locus Name, Keywords, Source, Organism, Authors, and Title of the Journal Article.

9.5.6.2 Virtual libraries

A virtual library is an organized set of links to items (documents, software, images, databases) resident in different computers on the network. The purpose of a virtual library is to enable users to find information that exists elsewhere on the network from one central ('virtual') location. Virtual libraries (VL) are a natural growth of the ability of modern client-server protocols (especially HTTP and Gopher) to provide seamless links to information anywhere on the Internet.

The World Wide Web Consortium (<http://www.w3.org>) holds the WWW Virtual Library (<http://www.w3.org/hypertext/DataSources/bySubject/Overview.html>). This is a distributed subject catalogue and includes a list of virtual libraries in a number of fields including those of interest to biodiversity. Other examples are 'Biosciences' housed at Harvard University in the United States (<http://golgi.harvard.edu/biopages.html>), and 'Forestry' (<http://www.metla.fi/info/vlib/Forestry.html>), among many others.

9.5.6.3 Special interest networks

A Special Interest Network (SIN) is a group of people and/or institutions who collaborate to provide information about a particular subject. SINS consist of a series of participating 'nodes' that contribute to the network's functions (Green and Croft 1994). More specifically the nodes carry out one or more of the following tasks:

- accept and store relevant, contributed material;
- provide some form of public access for users;
- provide some unique information, or mirror other sites;
- provide organized links to other nodes; and
- co-ordinate their activity with other nodes.

For research activity, SINS are the modern equivalent of learned societies and perform such functions such as publication (journals, newsletters, data sets, software), library services (links to both on-site and off-site sources), communication (mailing lists, workshops and conferences), and other services (specialist advice, data analysis). A good example of a SIN is the European Molecular Biology Network (gopher.felix.embl-heidelberg.de). EMBNet is a special interest network that serves the European molecular biology and biotechnology research community. It consists of nodes operated by biologically orientated centres in different European countries. It features a number of services and activities, especially genomic databases.

Various projects are also putting into practice the SINS concept. FireNet (<http://online.anu.edu.au/Forestry/fire/firenet.html>), for example, is a SIN concerned with all aspects of landscape fires (Green *et al.* 1993) and the Biodiversity Information Network – BIN21 (<http://www.bdt.org.br/bin21/bin21.html>) was established to facilitate the access of all levels of information, from molecular to biosphere (Canhos *et al.* 1992). BIN21 is developing affiliations with and network links to organizations that are already carrying out related activities (Canhos *et al.* 1994).

9.5.7 CD-ROM and diskette

The distribution of information on CD-ROM has emerged as a major form of information exchange in recent years, a trend that is set to continue. This is mainly due to the enormous storage space offered by a single CD-ROM disk, which is quite adequate to store comprehensive collections of journal abstracts, whole learned scientific journals, books, encyclopaedias, and other information sources, which up until now have been distributed as on-line databases and printed text. See Table 9.5-6 for a list of selected CD-ROM products.

Table 9.5-5: Selected international metadatabases.

-
1. The *CIESIN Catalog Service* allows search and retrieval of metadata concerning the environment. Data available through the system will consist primarily of CIESIN holdings and the holdings of CIESIN’s Information Co-operative partners and those that are referenced by the US NASA Global Change Master Directory.
 2. The *European Environment Agency* is the European Union body charged with harmonizing environmental data and distributing it to EU institutions, Member States and the public. Collecting and distributing knowledge about relevant sources of environmental data and information is to be done through a Catalogue of Datasources, based on collaboration mainly between the Agency, the National Focal Points of the Member States and a limited number of international organizations.
 3. The *IUCN Environmental Law Centre* monitors and maintains databases on legal trends and developments in the environmental field, including international agreements, binding instruments of international organizations, national legislation and legal literature.
 4. The *NASA Global Change Master Directory* includes information on a wide range of data sets relevant to the study of global change.
 5. The *Global Environmental Network Information Exchange* (GENIE) aims to allow those with knowledge of data holdings to make their knowledge available to other researchers. Although no single centre will hold all the information available in the system as a whole, GENIE will assist users to answer a variety of queries.
 6. The *Global Land Information System* (GLIS) is an interactive computer system developed by the US Geological Survey (USGS) for scientists seeking information and access to data pertaining to the Earth’s land surface that can be used in continental and global scale Earth science and global change studies.
 7. The International Referral System (IRS), later renamed The Global Environmental Information Exchange Network or *INFOTERRA*, was established in 1975 to ‘facilitate the exchange of environmental information within and among nations’. It is under the auspices of UNEP.
 8. The *International Plant Genetic Resources Institute* (IPGRI) maintains a database on the known Directories of Germplasm Collections. These directories list the germplasm holdings of specific crops and food plants in institutes around the world. The information aids scientists in making contact with other workers involved in the same crop.
 9. UNEP/GRID was established in part to facilitate access to global and regional GIS data sets. GRID is developing a metadatabase of its data holdings.
 10. The *HEMDisk* produced by the UNEP Office of *Harmonization of Environmental Measurement* (HEM) is derived from three surveys to identify environmental monitoring agencies, particularly those with international scope, outlining their organizational objectives, the nature of the monitoring programmes, and providing a contact address.
 11. The *World Federation for Culture Collections* (WFCC) is a federation of the International Union of Microbiological Societies. One of its aims is to create a global network of information services charged with compiling and disseminating data on cultures. Another is to address practical questions such as the impact of postal regulations, quarantine rules, patent laws and public health concerns on culture distribution. Computerized Information Services operated by the Federation include the Microbial Strain Data Network, and publications include the *World Directory of Collections of Micro-organisms* and the *Living Resources for Biotechnology*.
 12. The *World Data Centres* were originally established to store information from ICSU’s 1957 International Geophysical Year. Currently, 27 WDCs are active collecting, archiving and disseminating data which encompass most facets of the physical global environment.
-

As people’s demand for information increases, CD-ROM has emerged as an excellent alternative to on-line access, video tapes and the printed word. Users can browse and search the database while familiarizing themselves with search techniques, without the pressure of mounting cost as occurs

with on-line access. Indeed, in some circumstances CD-ROM is now replacing on-line usage completely. However, while on-line databases normally have frequent updating schedules, updated CD-ROMs may not be released frequently or at all, causing them to become obsolete over time.

CD-ROMs are normally acquired for a one-time charge. This may give the user outright purchase or may be a type of lease agreement. As such they offer more budgetary control and no additional costs are incurred for frequent use. Thus if used frequently, the initial high cost can be recouped. In some cases, favourable charge rates may be offered to developing country customers.

Although many electronic information sources are now being shipped on CD-ROM, the large capacity of this medium is rarely used. In some cases, the information will fit onto a small number of diskettes which can be installed directly onto the hard disk of the user's computer. Provided the requisite hard disk space can be afforded, this solution has the advantage that access to the information is very

Table 9.5-6: Selected CD-ROM and diskette products with global or regional data sets related to biodiversity.

-
- **African Development Indicators** (Diskette). Published by World Bank. Statistical data for 242 indicators of development in 52 African countries. Indicators in two groups, economic and financial, social and environmental.
 - **AgECONCD** (CD-ROM). Published by CAB International. Aspects of economics and policy related to agriculture, rural development, environment and forestry.
 - **Agricola** (CD-ROM). Published by SilverPlatter. The National Agricultural Library database concentrates on agricultural subjects but includes related material such as ecology. The references are drawn from journals, books, theses, patents, audiovisual materials and technical reports. The CD corresponds to the printed product, *Bibliography of Agriculture*.
 - **Agris** (CD-ROM). Supplied by SilverPlatter. FAO produces an on-line product by this name in addition to the CD-ROM and the printed product *Agrindex*. Centres in over 100 countries contribute. The coverage is primarily agricultural but relevant aspects include economics, development, forestry, aquatic sciences and fisheries and natural resources. The principal sources are books, journal articles and conference proceedings. Searchable in English, French, Spanish.
 - **AGRISEARCH** (CD-ROM). Supplied by SilverPlatter. This product brings together five databases on research and development projects in agriculture food and nutrition:
 - CRIS produced by US Department of Agriculture describes projects within the Department and other agricultural, forestry and veterinary institutions.
 - ICAR produced by the Canadian Agricultural Research Council, a bilingual database of Canadian research projects.
 - AGREP produced by the European Commission, the Agricultural Research project database contains records of European research in agriculture, fisheries, food science and forestry.
 - ARRIP the Australian Rural Research in Progress database covers recent Australian research in agriculture, horticulture, forestry, fisheries, food technology and soil science.
 - SIS produced by the Special Program for African Agricultural Research, contains records for research in all areas of agriculture, with emphasis on the sustainable use and development of renewable natural resources.
 - **AGROSTAT-PC** (Diskette). Supplied by FAO. Provides access to world-wide time series statistics on agricultural production and trade; land use and inputs; nutrition; forestry; and population. AGROSTAT-PC is designed to supplement FAO's print publications and to provide faster dissemination of data for longer time periods.
 - **Antarctica - digital database** (CD-ROM). Available from British Antarctic Survey. The database is a seamless digital map of Antarctica with the most up-to-date and complete coastline of the continent from which maps can be generated and used as a topographic framework to provide a common base for spatial data. Requires PC ArcView, PC ARC/INFO, PC ArcCAD software.
 - **Aquatic Sciences and Fisheries Abstracts (ASFA)** (CD-ROM). Published by SilverPlatter. A product of co-operation between UN agencies and national research centres which corresponds to three printed products – *Aquatic Sciences and Fisheries Abstracts*, *Biological Sciences and Living Resources* and *Ocean Technology Policy*, and *Non-Living Resources*. As the titles of the printed products imply the main subject areas covered are global developments in management of marine, freshwater and brackish water environments. The main sources are journal articles, books, conference proceedings and technical reports.

- **Biological and Agricultural Index** (CD-ROM). Published by H.W. Wilson. The CD-ROM corresponds to *Biological and Agricultural Index*, which comprehensively indexes over 200 key scientific journals. The main pertinent areas covered are: agriculture, biology, botany, ecology, entomology, fishery sciences, forestry, genetics and zoology.
- **Biological Abstracts/RRM on Compact Disc** (CD-ROM). Supplied by SilverPlatter. The corresponding printed product is the pre-eminent source of literature on biological subjects, *Biological Abstracts/RRM (Reports, Reviews, Meetings)*. As such its coverage includes agriculture, botany, ecology, environmental biology, forestry, genetics, systematic biology and zoology. The coverage is drawn from journals, books, papers from meetings and symposia, and reports. Reviews of books can be used to determine the relevance of sources for purchase.
- **CABCD (CAB Abstracts)** (CD-ROM). Supplied by SilverPlatter. In this form all the CAB Abstracts journals are included. The subject coverage is agriculture and forestry including economics. Separate CD services are produced on some topics e.g. *TREES-CD*, *PlantGene-CD* which cover much longer time periods.
- **Compact International Agricultural Research Library Basic Retrospective Set 1962-1986** (CD-ROM). Published by CGIAR. This bibliographic and reference database corresponds to the publications of International Agricultural Research Centres and includes full text, references, statistics and graphics. The main subject covered is forestry.
- **Directory of Country Environmental Studies** (Diskette). Available from World Resources Institute. The diskette corresponds to the printed document of the same name but includes material from both the 1993 and previous editions. The directory lists selected environmental and natural resource assessments, profiles and strategies for developing countries. These may relate to biodiversity, forestry and natural resources, land forms and use.
- **Earth Summit** (CD-ROM). Published by IDRC. All documentation relating to the United Nations Conference on Environment and Development is included. The documentation includes the texts of the conventions, Agenda 21, reports of NGOs, and documentation from the preparatory stages, such as the country reports.
- **Endangered and Threatened Species** (CD-ROM). Published by Quanta Press. This CD contains both text and images for all plants or animals listed in the US Endangered Species Act. The coverage also includes wildlife recovery programmes, status reports, scientific names and major programmes.
- **Families of Flowering Plants** (CD-ROM). Published by CSIRO, Australia. The CD is aimed at those attempting to identify and classify flowering plants. It uses an interactive program, INTKEY. For every level there are morphological descriptions. The CD includes comprehensive information on plant distribution.
- **Fish of the North-Eastern Atlantic and the Mediterranean** (CD-ROM). Published by UNESCO. For approximately 1500 species of fish, species name, habitat, distribution is given in full-text format with images where appropriate.
- **Fish and Fisheries Worldwide** (CD-ROM). Published by NISC. This product depends on information provided by the US Fish and Wildlife Service, JLB Smith Institute of Ichthyology and National Fisheries. The main aspects of interest are fish ecology, distribution and economic aspects.
- **FishBase** (CD-ROM). Published by ICLARM. This database includes information on all aspects of ichthyology and of fish as resources, e.g. nomenclature, distribution, ecology, reproduction, ecology, mortality.
- **GEOBASE** (CD-ROM). Published by Elsevier Science. This CDROM combines six printed sources on a family of disks. Three speciality subsets of the data are available on separate disks, two of which are relevant, i.e. Geography (human and physical geography including international development) and ECODISC, focusing on all ecological sciences. Material covered is drawn from journals, books and reports.
- **HEMDisk** (Diskette). Published by UNEP. The information on this diskette corresponds to three publications, i.e. *Directory of Organisations and Institutes Active in Environmental Monitoring*, *A Survey of Environmental Monitoring and Information Management Programmes of International Organizations* and *A Survey of Organizations and Laboratories Manufacturing Supplying or Using Reference Materials for Environmental Measurement*. The main access point in the printed publications is by institution name: in electronic format searching is greatly enhanced.

Table 9.5-6: Cont.

-
- **Index Kewensis** (CD-ROM). Published by Oxford University Press. The reference work is the most comprehensive registry of plant names, including family, genus and species. As the original publication and all 19 supplements are on one CD-ROM, searching is greatly enhanced.
 - **Life Sciences Collection** (CD-ROM). Supplied by SilverPlatter. The CD product corresponds to 20 different abstracts journals whose coverage includes entomology, ecology and agriculture. The product is promoted to those looking for an interdisciplinary approach to the life sciences.
 - **Multimedia Encyclopedia of Mammalian Biology** (CD-ROM). Published by McGraw-Hill. This corresponds to the 1990 edition of *Grzimeks Encyclopedia of Mammals*. In addition, it includes video and audio sequences which were mainly provided by the BBC Natural History Unit.
 - **Natural Resources Metabase** (CD-ROM). Published by NISC. The database is compiled from more than 40 US and Canadian government databases. This compilation concentrates on the effects on natural resources (wetlands, Pacific islands, ecosystems, national parks, endangered species etc) of human actions and changes in natural phenomena primarily in the US, Canada and the Pacific.
 - **Oceanographic and Marine Resources Vol. 2** (CD-ROM). Published by NISC. The bibliographic references cover selected material from 1807 to 1959 and are complete from 1960 to date. The relevant subject areas are marine resources, law and policy.
 - **PlantGeneCD** (CD-ROM). Published by CAB International. This joint CAB International and International Board for Plant Genetic Resources product covers the literature of plant breeding and genetic resources. The main sources are journal articles, books, reports and conference proceedings.
 - **PROSPECT (Programmed Retrieval of Species by the Property and End-use Classification of their Timbers)** (Diskette). Published by Oxford Forestry Institute. Primarily it is a database of wood properties which has been developed to support the requirements of those involved in forest management, timber conversion and utilization. Many of the data on over 1000 species are derived from the literature held in the Oxford Forestry Institute.
 - **SESAME** (CD-ROM). Published by CIRAD. This bibliographic database covers French-language literature, although most entries have English titles added, on sub-tropical and tropical agriculture and rural development. Many of the approximately 150 000 references are unique to the source.
 - **Smithsonian on Disc** - Catalogue of the Smithsonian Institution Libraries on CD-ROM (CD-ROM). Published by GK Hall. Some of the 16 libraries of the Smithsonian hold material very relevant to conservation of biological diversity. Although a US institution, its coverage extends far beyond national boundaries.
 - **TREECD** (CD-ROM). Published by CAB International. This product, comprising one CD, corresponds to the abstracting service *Forestry Abstracts* since its inception in 1939 and includes all *Forest Products Abstracts* and *Agroforestry Abstracts*. In all over 300 000 abstracts are included.
 - **TROPAG AND RURAL** (CD-ROM). Supplied by SilverPlatter. In printed form *Abstracts on Tropical Agriculture* and *Abstracts on Rural Development in the Tropics* cover the same ground. The subject area, as the name suggests, is literature about practical aspects of agriculture in tropical and subtropical regions and rural development including economic policy and planning, environment and natural resources. The product's strength is its coverage of these subjects in France and Francophone developing countries.
 - **Wildlife Review and Fisheries Review** (CD-ROM). Published by NISC. As the name suggests, the printed products *Wildlife Review* and *Fisheries Review* form the basis for this CD-ROM, which covers international literature on mammals, birds, amphibia and reptiles, habitats, management techniques, natural history, hunting and propagation. Good taxonomic and geographic indexing helps searching. No Abstracts.

- **Wildlife Worldwide (National Information Services Corporation)** (CD-ROM). Published by NISC. The product corresponds to ‘Wildlife Review’, the indexing service produced by US Department of the Interior, National Biological Survey and on-line sources e.g. Waterfowl and Wetlands. The product covers the literature on mammals, birds, reptiles and amphibians. No abstracts of the literature are provided.
- **World Resources Data Base** (Diskette). Published by World Resources Institute. This source gives a substantially expanded version of the data in Part 4 of the printed volume of *World Resources*. One can browse or extract data with the aid of a number of mathematical or statistical functions from more than 500 variables (e.g. forests and rangeland, biodiversity, landcover, agriculture, number, species density, protected areas, trade, habitats) for almost 200 countries.
- **Zoological Record on Compact Disc** (CD-ROM). Supplier SilverPlatter, Microinfo. This product corresponds to the print one, *Zoological Record*, which concentrates on every major area of zoology with emphasis on animal biology. In addition to covering over 6000 international serials conference proceedings, books and reports are carefully screened for inclusion.

fast: CD-ROM drives are ideal for storing large amounts of data, but are currently slower than hard disks.

9.5.8 Directories of data sources

There is a range of directories, catalogues and indexes available to help in locating sources of information on species, habitats and genetic resources. For example, the directories of plant germplasm collections list the germplasm

holdings of specific crops and food plants in institutes around the world, including root and tuber crops, cereals, vegetables, industrial crops, tropical and subtropical fruits and tree nuts, temperate fruits and tree nuts and forages. The information in most of these directories serves to direct scientists and others requiring such information to more detailed sources of information, and assists them to make contact with other individuals working in the area of interest (see Table 9.5-7).

9.5.8.1 *Species names/described species*

The main compilations of species names are given in Table 9.5-8. These comprise a mixture of catalogues (mostly from the last century) and on-going indices, although these do not exist for all groups of organisms. Detailed catalogues for particular groups are also published occasionally.

Those describing new species are under no obligation to register the names of those species with any authority (with the exception of bacteria). The International Registration Authorities for the 'cultivar' names of cultivated plants operate only as a voluntary system, and no authorities exist at all for many genera. However, registration has been approved in principle from the year 2000 onwards, as a requirement for all names in botanical groups, with details of mechanisms to be drawn up by the International Association for Plant Taxonomy. The concept is also under discussion for animal species (Hawksworth *et al.* 1994). Whether or not registration systems can be realized will depend upon appropriate international funding becoming available.

The current compilations of names, and also registers of names, are nomenclatural devices rather than a continuously updated list of scientifically accepted species with the "correct" name. It is such global master species databases that are the real need of those involved in the inventorying, description, communication and regulation of biodiversity and its uses. This type of information does exist for many groups, but is uncoordinated and scattered though a variety of databases based in different countries (Bisby 1993). With advances in computing and communications technology, it is now technically feasible to consider collating the many existing data sets, so as to provide access to accepted species databases covering all groups of organisms.

That such a major compilation could now be achievable is indicated by two recent events. First, the production of a list of 28 041 generic names for non-fossil botanical groups prepared with the help of over 200 plant taxonomists (Greuter *et al.* 1993), and second the establishment of a mechanism to produce a list of the accepted species of the world's vascular plants (Burnett 1994). In recognition of the international need for a global synthesis of the organisms now known, the 1994 IUBS General Assembly unanimously agreed to include the production of a global master species database in its scientific programme for 1994–97. Funding for this is now being sought.

9.6 Legal aspects of information management

9.6.0 Introduction

As the introduction to this Section describes, several international agreements impose obligations on governments and private organizations in the area of biodiversity information management and communication. In addition,

international law has limited what public and private organizations can do with such information. The goal of this chapter is to describe the major sources of international law as well as some of the principal legal issues associated with biodiversity information management.

The topic is simultaneously narrow and broad. It is narrow in the sense that legal aspects of biodiversity information management relate primarily to the evolving intellectual property regime for numerical data and published information, both in hard-copy and digital electronic formats. At the same time, biodiversity information is inextricably linked to many other kinds of activities and issues, including technology transfer, natural resource management and trade, remote sensing and telecommunications, and national security. Thus, while the following discussion focuses specifically on law pertaining to global biodiversity information, references are made to related, yet directly relevant, legal regimes and issues.

9.6.1 Sources of international law

International law has both public and private dimensions. The public domain (9.6.1.1) regulates the activities and relationships of nation states and intergovernmental organizations. Within the context of public law, private law (9.6.1.2) controls the activities and relationships of individuals, corporations and nongovernmental organizations.

9.6.1.1 Public law

The sources of public international law are, in descending order of priority: international conventions, international custom, general principles of law, and judicial decisions and teachings of the most highly qualified publicists (International Court of Justice Statute 1948). The two most important of these are described below.

International conventions. Like private contracts, treaties – or international conventions – are not sources of law, but sources of rights and obligations of the signatory parties (Fitzmaurice 1958). However, because they constitute the most binding form of legal instrument, they are looked to first in the resolution of disputes among nation states.

The treaties that are most directly relevant to biodiversity information management are the Convention on Biological Diversity, particularly Articles 15, 16, 19, 20 and 21 (UNEP 1992), and the existing system of international intellectual property law, which is composed of several treaties that provide nations with legal mechanisms for protecting, under their own laws, each others' copyrighted works and similar materials. The treaty that is most applicable to the legal protection and control of biodiversity information is the Berne Convention for the Protection of Literary and Artistic Works (Berne Convention 1886), which, as of mid-1994, had 105 members (IITF 1994). The intergovernmental

organization responsible for administering this convention and other agreements regarding intellectual property is the World Intellectual Property Organization (WIPO). While traditional copyright and patent laws do not apply to numerical databases of the kind discussed in this section, the subsidiary forms of legal protection for databases are discussed below.

There are several additional treaties relevant to biodiversity information management. These include the United Nations Charter (UN 1948), which provides the broad institutional and legal context within which the Convention on Biological Diversity is framed, and the Uruguay Round of the General Agreement on Trade and Tariffs (GATT 1993), the principal legal forum for resolving trade disputes, including those concerning biological resources. The Convention on International Trade in Endangered Species (CITES 1973), the major international agreement prohibiting trade in endangered species, is also relevant as it requires national governments to collect, manage and communicate biodiversity information in a certain prescribed way.

In addition to treaties, executive agreements – also referred to as Memoranda of Understanding (MOUs) – between the government agencies of two or more nations, are an important source of specific rights and obligations. Although these agreements do not have the legal binding force of treaties (not a universally held view), they do reflect high-level policy decisions of their participants' executive branches. In the area of biodiversity information management, MOUs will primarily define the scope and content of specific bilateral relationships. The aggregation of these agreements will ultimately be the most important source of what is known as international custom.

International custom. International custom derives from the general practices of nation states accepted as law (International Court of Justice Statute 1948). Evidence of the general practice of states may be found in MOUs, the consistent and repetitive behaviour of states, and the official acts of states, including the promulgation of national laws. Most nations, for example, have environmental and natural resource laws and regulations that seek to balance competing interests such as environmental protection, economic exploitation, public health and safety, and national security. Together, these national laws contribute to the evolution of international custom.

As formal intergovernmental organizations have proliferated in the latter half of this century, there has been a tendency to accord similar legal status to the behaviour and official acts of these organizations – a significant factor with respect to biodiversity information. For example, there have been a number of relevant UN General Assembly Resolutions since the early 1970s (see, *inter alia*, the Stockholm Declaration, 1972; the World Charter for Nature, 1982; the Rio Declaration, 1992; Agenda 21, 1992;

and the UNEP Forest Principles, 1992). Although these resolutions are not legally binding, they reflect an emerging global environmental ethic and incipient international environmental law that, over time, will likely achieve the status of customary international law (see Tinker 1990).

A large body of customary law has developed around the subject of intellectual property (although, as noted above, copyright and patent provisions generally apply to information but not numerical data). While the foundation international agreement on intellectual property – the 1886 Berne Convention – has existed for more than 100 years, nations have interpreted it quite differently, and individual approaches continue to evolve rapidly today (see Stewart 1989). A notable example of such differences is the fact that information produced by the United States Government is not subject to copyright, whereas copyright provisions usually apply to the information published by most other governments. Moreover, the rapid rise in the use of national and international electronic networks has raised new issues regarding the legal protection of digital data and information (IITF 1994), which are likely to require changes to the Berne Convention and other intellectual property agreements under the WIPO umbrella.

Numerical databases present a special challenge. The huge increase in the amount of observational environmental data – brought about by highly sophisticated sensing instruments and facilitated by continuous advances in computer and communication technologies – has created pressure to develop and harmonize new legal constructs for their effective management. As in the case of environmental law, a number of competing interests have made this difficult. On the one hand, the public interest in encouraging the broadest possible access to information on biodiversity and other environmental problems has led to the treatment of numerical databases as public goods, unencumbered by legal restrictions on their dissemination and use. Within the scientific research community, it has been customary to openly share many types of geophysical data, although this tradition has not been as strong in ecological research. In addition, many environmental treaties have provisions for the open exchange of scientific data, including environmental satellite data (see Uhler 1986).

On the other hand, businesses and certain government agencies have contrary interests – driven by commercial opportunities or national security – regarding the sharing of numerical databases. Commercial data have generally been protected through private, contractual licensing and 'trade secrecy' provisions while governments have applied national security laws with severe penalties to restrict dissemination of certain types of data, sometimes for spurious reasons. An important development in the economic protection of data is the European Union's proposed Directive on Legal Protection of Databases (EC 1992) – discussed

further below – which would provide a legal framework for the economic exploitation of numerical databases within Europe.

Customary law that has arisen in the area of international trade will also be an important source of law regarding business aspects of biodiversity data and information. Although the General Agreement on Tariffs and Trade (GATT) provides the principal dispute-resolution mechanism for the nations that are party to it, most of them have separate bilateral or regional trade agreements regulating specific commercial transactions, including those involving biodiversity resources and related data and information.

9.6.1.2 Private law

Much of the research that will generate biodiversity information in the future will be conducted by private-sector parties, including researchers employed by private universities, corporations, and not-for-profit, non-governmental organizations. These parties will also in many cases become the custodians or owners of that information and will control its access and distribution.

How private parties manage biodiversity information will be determined in part by the public laws outlined above as well as by private contracts. Disputes among these parties are generally settled in formal legal proceedings. These proceedings will eventually result in a body of legal precedents spanning multiple jurisdictions.

Although each private contract regarding biodiversity information will apply only to its signatory parties, some particularly innovative contracts are likely to serve as models. One such agreement, between Merck & Company, Inc. and Costa Rica's Instituto Nacional de Biodiversidad (INBio) (Merck 1991), is already considered a potential model for how the biotechnology industry and nations with diverse biological resources might co-operate under the framework of the Convention on Biological Diversity (see Joyce 1991). Signed in 1991, the agreement requires Merck to provide US\$1 million to INBio and meet other specific conditions in exchange for exclusive rights to screen for potential pharmaceuticals certain, specific taxonomic groups of plants, insects, and other organisms collected by INBio researchers. Over time, such contracts as well as adjudicated disputes should generate a worldwide body of evidence of customary practices in the private sector.

9.6.2 Major legal issues

To summarize all the major legal issues surrounding biodiversity information management in all the world's jurisdictions would be futile. Instead, this section will discuss relevant legal principles in as general terms as possible. Frequent reference is made to United States laws, while pointing out distinctions with major international trends.

9.6.2.1 Intellectual property rights

The law of intellectual property is designed to protect the legitimate rights of those who produce original works, thereby providing incentives for that work. Copyright, patent and trademark are the primary formal mechanisms within this body of law.

Copyright requires very little in terms of formal legal requirements. However, a recent US Supreme Court case shows that, in the United States, the requirements that copyrighted work be original and involve the creative process are strictly construed (*Feist Publications v. Rural Telephone*). The case is particularly pertinent to computer databases, where the elements of originality and creativity tend to be minimal. In addition, the so-called 'Idea Expression' merger doctrine of US copyright law – which holds that if the expression is the same as the physical fact, then no original expression is made and the work cannot be copyrighted (*Mason v. Montgomery Data*) – will play an important role in assessing the eligibility for copyright protection of biodiversity databases, at least in the United States.

In the European Union, a 'right to prevent unfair extraction' has been advocated in a directive on the legal protection of databases. The directive defines this unfair extraction right as the 'right of the maker of the database to prevent acts of extraction and reutilization of material from the database for commercial purposes'. The US Register of Copyrights has indicated that a similar right of extraction might be considered in that country.

Patents traditionally have been used to protect property rights related to devices or machines. Today, however, computer software has blurred the distinction between machines and information, and patents as well as copyright are now used to protect certain aspects of computer software. Information and software are often difficult to separate, either because data are formatted such that practical access depends on the use of particular software or because they are included with the software. This means that those seeking access to – or seeking protection of their rights to – biodiversity information may have to deal with both patent and copyright law today.

Where patent and copyright protection is either not available or impractical, contracts may be used to secure property rights to data. Contracts relating to computer software or data, usually referred to as licences, establish such terms as cost and restrictions on redistribution. The important distinction between a licence and copyright is that the latter arises automatically and applies to any party, while the former must be created by contract and applies only to the parties to that contract.

The emergence of wide-area computer networks has introduced many still-unanswered legal questions with respect to information access. Computer networks – in particular, global computer networks – have increased the

fluidity and accessibility of data by orders of magnitude. This has made protecting legitimate property rights far more difficult from a technical point of view. In addition, the choice of intellectual property law among the world's hundreds of jurisdictions portend as a legal morass. While the basic legal principles underlying licences, copyright and patents are likely to remain unchanged, applying and enforcing these principles will have to meet new challenges.

9.6.2.2 *Freedom of information and public databases*

The rules that govern access to public information are often different from those governing private information. As noted above, government information is generally viewed as belonging to all citizens as a public good. In many countries, open records or freedom of information laws permit public access to government information for a nominal cost. Such laws are based on the premise that access to information is necessary for citizens to make governments accountable for their actions. Thus any barriers to information access, including the charging of fees, are viewed with the suspicion that they are being used by government to operate 'behind closed doors'.

While access to information is generally important to biodiversity conservation and management, there may be some exceptions. If the precise location of an endangered species is available to the general public, for example, that species could be placed at risk, and some restrictions on open access may be required.

In countries such as the United States, Canada, Australia and New Zealand, access to governmental information is governed by statute. One example is the US Freedom of Information Act (FOIA), which provides that the final opinions, policy, and any records reasonably described shall be disclosable to the public, subject to such exemptions as matters of national defence, commercial trade secrets, and personnel and medical information.

Although many national governments feel free to charge fees for public access to government information, FOIA allows agencies to charge only for the cost of search and review. However, because information is increasingly being regarded as a commodity with value, some experts argue that even public information should be paid for according to its value and that such payments can be made without compromising the principle of keeping government accountable. They say that it is the prohibition of information access, and not the charging of reasonable fees for that information, that poses a danger to democracy.

9.6.2.3 *Privacy*

The pervasiveness of computerized information has generated considerable concern for privacy. Although biodiversity information would seem to pose less of a

threat than that directly related to people, the breadth of information needed for biodiversity conservation and management means that privacy conflicts are bound to arise. Many corporations and individuals, for example, may resist the collection of information by outsiders on private land, yet collecting such information may be essential to the effective management of biodiversity found there and therefore be required by law.

In the United States, privacy statutes have emphasized access to government information by the individual in order to ensure that inaccurate, and therefore potentially damaging, information can be corrected. Statutes have also limited the mixing and matching of information among agencies to protect against unanticipated use of personal information by the government. When a conflict between FOIA and privacy occurs, the law has consistently favoured disclosure over nondisclosure.

US privacy laws applicable to the private sector primarily concern the practices of financial credit reporting companies, so that even the relatively limited protection with regard to public data are not present in the private sector. In contrast, the European Union does not differentiate between the private and public sectors, but provides universal standards to control the dissemination and matching of information (Anderson 1992).

9.6.2.4 *Liability*

In any enterprise – including information management – legal liability can be a concern to participants. Liability arising from contracts or the licensing of information is relatively obvious as exposure is limited to the parties and terms of the contract. The law of negligence or intentional wrongdoing, referred to as tort law, includes liability for negligent or intentional misrepresentation. Defamation or libel can also result from the tortious use of 'information'. Private disseminators are generally subject to these rules of law.

With regard to public information, state courts in the United States in general have been reluctant to impose liability on government agencies when erroneous information has damaged a citizen, although courts in some states have nevertheless done so. At the US federal level, the Federal Tort Claims Act specifically exempts federal agencies from liability for misinformation.

In the United States and other common law jurisdictions, tort law is based mainly on common sense and logic. If the circumstances under which a government agency or private party provides information to a person creates a reasonable expectation of reliability – and that person relies on the information and is harmed – it is likely that a legal remedy for the injury can be found. Whether or not liability can be avoided, those who disseminate information should always be sure to notify potential users of its limitations.

9.6.2.5 Authentication and admissibility of data

Although law is often thought of as lagging behind technological developments, a number of courts in the United States have recognized the admissibility of electronic documents in official legal proceedings. Because the requirements for admissibility are the same as those for hard-copy materials, it has generally not been necessary to pass new legislation to accommodate electronic materials (Weiss 1994).

Documents – both hard-copy and electronic – are generally admissible if they can be shown to be reliable and what the litigant purports them to be. To be sure, this requirement creates some difficulties given the comparatively ephemeral character of electronic information. In US law, a common requirement for the admissibility of electronic documents is that of demonstrating that the documents are used in the regular course of business and are therefore reliable. Meeting this and other criteria for admissibility underscores the importance of sound information management.

9.7 Institutional capacity development

9.7.0 Introduction

While there is no question that nations must develop the capacity to manage and communicate biodiversity information, there is no universal model that demonstrates how to do this. Every country faces a unique situation, and national planners must devise their own individual strategies based on these conditions. Starting from this premise, this chapter will discuss some of the issues decision-makers should consider when developing an information management strategy, no matter what model they have adopted.

The obvious first step is to look at what in-country institutions already do in this area. Institutions that manage biodiversity or other relevant data are likely to be one of two types: data centres whose activities are determined by the demands of specific users (a census bureau would be one example) or more-thematic, data-generating institutions committed to long-term goals (such as national meteorological or regional development agencies) whose data would be valuable to a wide range of users. Planners of information management systems must be aware of all these institutions – found throughout government, nongovernment and private sectors – and devise a strategy that co-ordinates their unique contributions. To facilitate co-ordination and the exchange of information, a central co-ordinating body should be identified. This body will have access to, and knowledge about, information held throughout the national network, but will generally leave control of information to the individual custodian institutions.

The following describes some issues that experience has shown should be considered when developing a national information management strategy. Those issues are: information needs and information resources available (9.7.1), institutional capacity (9.7.2), technology selection (9.7.3), human resources and training (9.7.4), and financing (9.7.5).

9.7.1 Information needs and information resources available

The most critical step in designing an information management strategy is to define clearly who the intended users are and what their specific information needs will be. Too often this step is overlooked or not well defined. The result can be that inappropriate information is collected while other, more relevant information is not collected, or that information is collected at scales either too detailed or too general for use by the intended audience. This does not imply that the collection of basic information without immediate uses is always inappropriate. Indeed, many major advances in knowledge come about in this way. However, given limited resources, priorities in information collection and management must be set at the outset.

Another major consideration is defining what information resources are actually available or easy to develop. In many parts of the world, very little detailed information actually exists about biological resources. Even the most basic information about which species are present and how they are distributed is often lacking or very patchy. Information about the genetic or ecosystem levels of biodiversity is even less well developed. Thus, along with defining the information that users may desire, there is the need to define what information is already available or open to collection in a cost-effective manner.

A significant challenge in defining information needs is that many prospective users are unaware of the range of possibilities and therefore have trouble articulating their needs. Conversely, they may be unaware of the technical limitations or costs – both direct and indirect – of developing certain types of information. To define accurately what types of information users desire or need, and what types of information are available or can be developed, an interactive, consultative process is necessary. Such a process serves to educate users about the different possibilities available, while simultaneously seeking to identify which of them are of greatest interest, applicability and ‘do-ability’.

Along with defining information needs and availability, it is also important to identify data-sharing possibilities. To the extent possible, information management strategies should seek to adopt standards that will facilitate information sharing (9.2.4), although the degree to which information actually will be shared depends upon many factors of a technical, institutional and policy nature.

Making use of standards that hold this option open, however, is highly desirable, particularly in light of recent advances in electronic communications and global collaboration.

9.7.2 Institutional capacity

While the network model of a national information management strategy relies on a diversity of specialized institutions, the effectiveness of the network as a whole depends on the quality of its components. Careful and honest consideration of institutional capacity is therefore a key to any successful national information management effort.

Long-term institutional support for information management efforts normally occurs only if the institution has a vested interest in the effort. Does the institution have a clear mission, and is this mission appropriate for or dependent upon the data management effort (i.e. is it either a producer or user of biodiversity information)? How will such an effort fit into both the strategic objectives of the institution and its operational plans? While information management can produce short-term results, ideally it should be carried out in a long-term context; this raises the question, is the institution stable or is it subject to abrupt changes or elimination altogether? Adequate financing is another, obvious ingredient in creating a strong and sustained information management system (9.7.5); does the institution have the authority to secure the resources necessary to develop and maintain its information management system?

Because most biodiversity information efforts will require extensive collaboration among individual researchers and institutions, the ability to co-operate with like institutions (both at home and abroad), and with institutions in other sectors, is critical. Related to this, it is important to avoid or minimize duplication of effort with other institutions, seeking instead to establish unique and complementary roles.

9.7.3 Technology selection: a double-edged sword

Sound information management principles are technology-independent. Over the past few decades, the increasing availability and power of electronic data processing has made the popular image of information management virtually synonymous with use of computers. Computers can, of course, greatly increase the speed and efficiency of information management tasks. However, virtually all the basic functions that a computer performs, can also be done manually, albeit more laboriously. The basic principles that govern biodiversity information management can be, and often are, successfully employed with non-electronic technologies. Indeed, such non-electronic devices as filing cabinets, libraries, card catalogues and paper maps still form the basis for much if not most information management throughout the world.

Computers and the applications they support – especially database management tools and geographic information systems – will continue to play an increasingly important role in the management, retrieval, analysis and dissemination of biodiversity information. However, it is imperative that the technology selected for any particular information management effort be appropriate to the needs of that effort and be sustainable given the institutional, human and financial resources available. The questions posed and information needs identified should define the technology selected, rather than vice versa. Sadly, far too many information management efforts start the other way – with technology in search of a question to answer, the proverbial tail wagging the dog.

Key issues to consider in the selection of appropriate technologies are initial and recurrent costs, operation and maintenance viability, flexibility and growth potential, and potential for technological dependency. Actual costs of operating sophisticated database and GIS systems are often grossly underestimated in programme planning. Typically, project planners focus on the initial hardware and software acquisition cost and do not adequately plan for the costs associated with training, operation, maintenance and, especially, data development.

Beyond cost, the viability of operating and maintaining a given technology in the place where it will be used is also critical. For example, are the necessary electrical and telephone systems (needed for access to most national and international computer networks) available and reliable? Will the components of a system operate as expected in the new working environment? (Cost and frequency of repair information, for example, is generally valid only in specific places.) If any components of the system do need repair, can those repairs be made in-country, or must the machinery be sent abroad (resulting in considerable expense and inconvenience)? To avoid the latter problem, information managers should, whenever possible, choose less specialized equipment that can perform the necessary functions and also be repaired easily in-country.

In many industrialized nations, the high cost of human labour provides strong incentives for the adoption of automated technologies that require only a few, highly qualified workers. Each country faces a unique situation in this area, however. When developing any national information management strategy, it is important to consider the cost of training and retaining workers – beyond the expense of equipment itself – when considering the adoption of an advanced technology.

To facilitate wise decisions in this area, countries are encouraged to share experiences with other nations with similar human-resource structures. Not only can countries share such experiences, but they can also share software, which saves resources and personnel time by either

enhancing existing software or conforming to software that has already been tested and used.

9.7.4 Human resources and training

Those planning and implementing biodiversity information strategies often fail to recognize the importance of hiring or training experts in the field of information management. Instead, they usually rely on re-training existing personnel who lack the essential skills or long-term dedication to the field. Ultimately, such compromises will limit the effectiveness of the overall programme, providing a strong incentive to find – or train – the proper people at the outset.

Staff expertise is essential in implementing and using information management programmes. For example, competent staff are required to operate whatever technologies are used, whether that includes computer databases, geographic information systems, or satellite-image processing. Expertise in some of these technologies is often in short supply in developing countries, and training personnel must be a part of the information management strategy. But these technical skills are scarce and valuable in many parts of the world and every effort needs to be made to spread these skills among more people and retain skilled people in the organization.

Unfortunately, staff turnover can become a serious problem in information management, especially in the public sector. Many staff who receive specialized computer training as part of such activities become competitive for, and take, positions with better-paying private companies. To solve this problem, staff members who receive training could be offered alternative incentives to stay in their current positions – stability or future career options, for example – if higher salaries are not an option. Other solutions could be to train more people than are actually needed, to require a minimum length of stay through a contract, or to adopt a different technology, less dependent on highly trained professionals who are in demand in other sectors.

Local availability of trained personnel might also be a criterion used when deciding on technology options: depending on the information problem to be solved, the most efficient alternative is to adopt systems for which trained staff are already easily available.

Individuals with training in the biological and ecological sciences are also in extremely short supply, especially in developing countries where career pathways in these fields have not previously existed. In the absence of these career opportunities, there is little incentive for bright university students to study biology or ecology rather than go into more traditional and lucrative fields such as medicine, law, economics or business. Staff with appropriate expertise are, however, essential to ensure that the biodiversity information is appropriately collected, interpreted and managed, and also of high quality. Development of local capacities in these fields is another critical, if long-term, need.

9.7.5 Financing

Developing an effective national information management strategy is likely to be expensive. A serious challenge to procuring the necessary funding is the difficulty of finding funds for infrastructure development as opposed to higher priority but shorter-term projects. This problem underscores the need, mentioned previously, to demonstrate a data-gathering institution's relevance to solving environmental problems. One way to do this is to develop, early in the course of institutional development, products that show the organization's long-term, practical relevance.

Another solution in certain cases is to require the user of biodiversity data to pay for the costs. This approach has the advantage that 'the market' determines what data are collected and gives appropriate 'price signals' to potential users of that information. An assumption here is that a mature, informed market exists in this sector, which is not necessarily so. In addition, there is usually a time lag between identifying a need for information and the collection of that information, meaning that user needs would seldom be met. It is unlikely that agencies would be motivated to collect information for which there may or may not be future demand, particularly if not in their own countries.

A further difficulty is that, if information is judged by potential users to be too expensive, then it will not be acquired and thus not be used in reaching decisions, which will be poorer as a result. Since the consequences of making bad decisions seldom, if ever, flow back to the decision-maker, the 'discipline' ordinarily exerted by the market is not effective, thus distorting the pricing mechanism.

An alternative strategy is to support organizations that make data collected primarily for their own corporate requirements available to others. This can be done either by directly supporting the costs of making data freely available or, alternatively, by allowing a data set custodian to recover the marginal cost of doing so. A disadvantage of the latter alternative is that the marginal cost may be roughly comparable with the overheads involved in its administration.

While financial strength is certainly important to the success of any information management effort, some financing strategies may work against an institution's long-term survival. For example, large influxes of funding can often exceed an institution's absorptive capacity, undermining rather than increasing its stability. Achieving financial stability often depends upon having a balanced mix of funding sources to buffer against drastic changes in any one source. In addition, it is highly desirable to have some stable core-programme funding to provide continuity during the inevitable cycles characteristic of more volatile project-level funding.

EXECUTIVE SUMMARY

Biotechnology provides important tools for biodiversity assessment and monitoring:

- Key molecular technologies for biodiversity assessment and monitoring include screening methods for various classes of compounds, and DNA fingerprinting.
- Applications of biotechnology can increase our understanding of biodiversity at several levels, ranging from the effects of habitat modification or population fragmentation on partitioning of genetic diversity, through definition of taxonomic boundaries, to understanding evolutionary relationships on a broad scale. It contributes to our understanding of processes that underlie patterns of biodiversity. In effect, biotechnology brings new levels of quality and refinement to inventorying and monitoring of the living world.

Biotechnology provides important tools for biodiversity conservation:

- *In situ*. Applications of biotechnology provide data critical for the best management solutions for species. They allow assessment of optimal or minimal population sizes for maintaining diversity, and best practices for augmenting wild populations through transfers from other wild populations or from captive breeding programmes.
- *Ex situ*. Biotechnology contributes to the quality and efficiency of *ex situ* conservation of biodiversity.
- Biotechnology increases the quality of *ex situ* germplasm collections. Samples characterized on the basis of DNA sequence rather than on phenotype can provide better coverage of existing diversity, and can provide a means of avoiding redundancy.
- Biotechnology is the entire basis for a class of non-living conserved collections, namely DNA libraries and sequence databases. It allows compact storage of large amounts of genetic information which are recoverable for conservation of utilization objectives.

Biotechnology provides important tools for biodiversity utilization for human benefit:

- Living organisms can be used as factories for specific products, targeted to a variety of production end uses, harnessed for environmental remediation, or used in industrial processes. Biotechnology applications can serve rural, manufacturing and extractive activities.
- *Biotechnology-assisted breeding*. Especially through use of genetic markers, biotechnology can both enhance and accelerate the breeding process.
- *Genetic engineering*. Although not a universal solution, genetic engineering is the most elegant way of improving domesticated breeds. Protocols for gene transfer are now becoming routine. Genetic engineering can be used, among other objectives, to increase productivity, control disease, eradicate pests and improve product quality or novelty.
- *Novel genes and gene products*. Biotechnology-based screening (bioprospecting) can increase our capacity to locate and benefit from useful genes and compounds in the biodiversity around us.
- *Environmental remediation*. Biodiversity is the key resource for rehabilitating degraded ecosystems. Biotechnology greatly enhances both the specificity and efficiency of remedial actions.

Biotechnology can impact on biodiversity in various ways:

- These impacts can be direct or indirect. Both for human benefit and for environmental conservation, the outcomes can be positive or negative. Importantly, there are realistic ways of assessing potential impacts, and therefore of gaining maximum benefits from biotechnology applications. The benefits can be realized for both industrialized and non-industrialized peoples and places.
- Direct impacts of biotechnology are ecological or evolutionary, and can be assessed by scientific methodology and tested experimentally. They could include introgression, weediness, pathogenicity, altered nutrient cycling and a range of responses in other species populations.

- Procedures exist in many countries for assessing the possible impact of release of genetically manipulated organisms. In general, these adopt a case-by-case approach, although generic *a priori* risk appraisal is becoming acceptable in some situations. Step-by-step approaches to risk assessment may be of little predictive value for assessing the risk of commercial releases. Careful definition of data required during experimentation and post-release monitoring is necessary.
- Risk reduction is achieved mainly by confinement. Measures for minimizing direct impacts on native ecosystems aim to impose specified limits on gene transfer, on exposure to toxic products and on direct invasion. Good containment possibilities exist, even for microorganisms. Past experience with release of conventionally bred varieties is often a good guide for best practice.
- Indirect impacts of biotechnology are predominantly socio-economic. They can be of major importance because of the way social systems drive our use of biotechnology and biodiversity. Risk assessment for indirect impacts should therefore be independent of that for direct impacts.
- Biotechnology can increase the value of genetic resources. In absolute terms these values may be limited, but value changes may lead to indirect effects.

These may include conflicts over ownership, including intellectual property; altered rates of utilization and therefore of resource conservation and environmental protection; and ethical debates on the acceptable scope of the biotechnology applications themselves.

- When biotechnology results in increased agricultural productivity, both positive and negative impacts can be predicted. These include changed pressures for cultivating new land, replacement of traditional landraces, and marginalization of fringe production areas through price changes.

Biotechnology has great potential to generate benefits, both environmental and socio-economic. It can enhance our understanding of biodiversity and our capacity to conserve, manage and utilize it. It can improve our production systems and the diversity of the amenities we desire. In general, however, its impacts on biodiversity may not be different in nature, but only in degree, from those of our traditional or conventional practices. These impacts may be direct ecological and evolutionary outcomes of biotechnology applications, or indirect, resulting from altered socioeconomic circumstances. The Convention on Biological Diversity calls for appropriate safeguards to ensure safe applications of biotechnology. We have a growing capacity to assess likely impacts, and to make informed decisions both for conservation of biodiversity and for equitable sharing of the benefits of biotechnology.

10.0 Introduction

For policy-makers with responsibility for the good management of their national or regional biological resources, **biotechnology** is of special importance as it can greatly influence the economic basis for many management decisions relating to these resources. Thus, for many managers the issue of the conservation of biodiversity is, in a practical sense, the issue of how biotechnology can best be applied to obtaining national or regional benefits from genetic resource conservation and utilization.

10.0.1 Definition

In the Convention on Biological Diversity, **biotechnology** is defined as ‘any technological application that uses biological systems, living organisms, or derivatives thereof, to make or modify products or processes for specific use’. Many countries have adopted the same or similar definitions. When interpreted broadly, biotechnology can therefore include traditional methods, for example in improving domesticated plants and animals by breeding; utilizing microorganisms for food and beverage processing, and disease control through inoculation; and biological control of pests.

Biotechnology can be defined more narrowly, however, to encompass new technologies that have a strong molecular basis. These include recombinant DNA technologies, rapid screening techniques for natural products, and sophisticated culture processes. In the context of applying biotechnology to biodiversity, now and in the future, to capture significant new benefits for humankind, these new technologies are of great importance, and are the major focus of this Section. Whilst the traditional methods are important, their significance is largely self-evident and it is not necessary to deal with them comprehensively here. The traditional methods nevertheless give us a strong background of experience against which to assess the merits and risks of biotechnology applications.

Throughout this Section, the term biotechnology generally refers to these new molecular technologies, even though they comprise only a subset of the more broadly defined biotechnology of the Convention on Biological Diversity. Because of its importance to policy-makers, this subset is the one that requires particular attention in the context of the Global Biodiversity Assessment.

Many people apply the term ‘biotechnology’ even more narrowly, strictly in the sense of using gene manipulation, especially genetic engineering, for human benefit and commercial gain. This is the facet of biotechnology that is perceived, perhaps wrongly, to have the greatest economic implications, and is the one that has the highest public profile. It is the facet of biotechnology most strongly linked with ethical issues and concerns about biosafety and most emphasis in Section 10 is given to this aspect. However,

this interpretation of biotechnology overlooks the important contributions it can make to our understanding, management and conservation of biodiversity, which are also outlined below. The somewhat broader definition adopted here is therefore much more relevant to all of the aspects of biodiversity covered by the Convention.

There is a broad range of terminology in biotechnology, including **genetic engineering**, **gene engineering**, **recombinant technologies**, **recombinant DNA technologies**, **molecular techniques/technologies**, **gene manipulation/transfer** and **transgenesis**, all of which have the same or similar meanings. A comparable range of terminology applies to the products of biotechnology, including **genetically engineered/modified organisms**, **transgenic organisms** and **transgenes**. For the purposes of the discussion that follows, these terms are more or less interchangeable.

10.0.2 Putting biotechnology in context

As part of the Global Biodiversity Assessment, the primary focus of this Section is on biodiversity, and the Section is structured accordingly. Specific details of biotechnologies can be found in texts or in recent reviews, and to provide here a structured account of all biotechnologies would obscure the main issues relating to biodiversity. For each particular biodiversity issue, only those new biotechnologies most relevant are introduced, and biotechnologies are dealt with generically where appropriate. This enables us to best understand how biotechnology provides ways to increase our knowledge base on biodiversity, to manage it, to utilize it, and to address the implications of its use.

This Section, in common to some extent with Section 7, differs from most other Sections of the Global Biodiversity Assessment in that its subject is certain *tools* that are increasingly being used to achieve various biodiversity objectives. The other Sections focus primarily on *issues* relating to biodiversity. Wherever the objectives of applying these tools are discussed below, there is a consequent overlap with the subject matter of the other Sections. In order to present a picture of the importance and implications of biotechnology for biodiversity issues, a selection of examples and case studies is presented below. This selection is limited both by space and by the overlap with other Sections. Where further detail and examples are discussed in other Sections, appropriate cross-references are provided. In particular, the applications of biotechnology have relevance for the issues discussed in Sections 2, 3, 11, 12 and 13.

Chapter 16 of UNCED *Agenda 21* (see Section 1) is devoted to biotechnology. It too makes a distinction between ‘modern’ biotechnology (DNA manipulation) and ‘traditional’ biotechnology. It sets out a suite of recommended programmes for:

- Increasing the availability of food, feed and renewable raw materials.
- Improving human health.
- Enhancing protection of the environment.
- Enhancing biosafety and developing international mechanisms for co-operation.
- Establishing enabling mechanisms for the development and environmentally sound application of biotechnology.

This Section of GBA is in harmony with the broad thrust of *Agenda 21* Chapter 16.

10.0.3 Multiple roles of biotechnology

The relationship between biotechnology and biodiversity is multidirectional. First, biotechnology provides powerful new tools for assessment of biodiversity. It is therefore playing an increasing role in identifying the biological resources themselves. Secondly, it gives us new methods and guidelines for conservation of biodiversity. Thirdly, it provides a greatly enhanced capacity for wise and efficient utilization of biodiversity, both as a genetic resource for production and in the remediation of degraded ecosystems. The chapters in this Section are structured to address these multiple roles.

10.0.4 Positive and negative impacts of using biotechnology

It is important to understand that by focusing on organisms resulting from applications of biotechnology, this Section does not imply that such organisms are necessarily dangerous. Neither does it imply that organisms resulting from traditional technologies, such as conventional breeding, are necessarily safe. As discussed below, many reviews have concluded that the assessment of risks of modified organisms should be based on the characteristics of the organism rather than on the means by which it was produced.

When applied prudently, biotechnology offers potential benefits to both developed and developing countries. However, there may be direct or indirect impacts that are negative, either for biodiversity itself or for the interdependent human communities. With adequate background knowledge, undesirable outcomes can be predicted, and with careful planning and good management they should be avoided or minimized. This topic is addressed in Section 10.3.

Biotechnology has great potential for improving our understanding and management of our biodiversity, for broad environmental and economic benefit. We can reasonably hold high expectations about embracing it, as long as we are able to identify the social and environmental risks and employ appropriate safeguards.

10.1 Accessing and using molecular DNA data on biodiversity

At its most fundamental level, biotechnology allows us to investigate critically the diversity of organic molecules, and the diversity of the primary structure of DNA, the genetic material itself. Our ability to isolate, clone and characterize specific DNA sequences from the vast array that exists in nature provides us with enormous opportunities. We can assay sections of genomes for genetic mapping purposes, and apply the knowledge to biodiversity assessment. The use of biotechnology to characterize living (and to some extent non-living) biological material can improve the quality of species inventories by, for example, refining the delineation of species and accurately estimating the scope of diversity within and between species (see Section 2.1).

Our knowledge and understanding of biodiversity is principally derived from biological collections, both living and non-living. Biological collections can be either *in situ* (conserving species by conserving habitat) or *ex situ* (conserving species by storage outside the natural habitat). The expansion of the knowledge base through applications of biotechnology to biological collections can not only enhance our understanding of the biodiversity of a region or country, but also foster practical approaches to its conservation. This chapter deals with technologies that can contribute to biodiversity assessment and conservation, and presents examples of how they may be applied. The substantive treatment of these topics is presented in Sections 2 and 13 respectively.

In order to maintain genetic diversity, *in situ* collections should have adequately large areas devoted to them, but in practice smaller carefully managed areas are usually set aside, and the role of biotechnology in this situation is of increasing importance. *Ex situ* conservation is achieved in many different ways, discussed in detail in Sections 8 and 13. A summary of the role of biotechnology in *ex situ* conservation is presented below. A recent development in data collection from *ex situ* collections is the storage of isolated DNA from endangered species, and its extraction from non-living samples is also discussed below.

Biological collections can also serve as sources of genetic material, either as genes encoding desirable characteristics (from living collections) or as storable DNA (from either living or non-living collections). They therefore provide the raw material for the genetic improvement of crop plants and animal breeding stock, and for other industrial applications. Utilization of biodiversity for these objectives is the major focus of this Section.

Although only 103 plant species provide 93% of the per capita food supply (Prescott-Allen and Prescott-Allen 1990), thousands more are grown for culinary and medicinal uses, as sources of fuel and fibre, as ornamentals and for many other purposes (see Sections 2.2.2 and 3.1.4).

Figure 10.1-1: Biotechnology applications in biodiversity assessment and management.

Many of the species providing the food supply are not understood at a detailed evolutionary or cytogenetic level, and wild relatives of these crops with potential utility are in danger of being lost owing to inadequate conservation (see Section 3.1.4). Extensive sampling of global biodiversity is therefore very important not only for characterizing the biodiversity itself but also for broadening the resource base for improving our production systems.

The roles of biotechnology applications in biodiversity assessment and management are summarized in Figure 10.1-1.

10.1.1 Key technologies

The key technologies that contribute significantly to the objectives described above are presented below as a general overview, comprising both chemical and molecular biological tools. The most important DNA methodologies for each objective are summarized in Figure 10.1-1. Several of these methodologies are described elsewhere in the GBA.

10.1.1.1 Chemical screening

Chemical screening for biological variation among organisms is an established technology, based on

classifying organisms by virtue of their chemical phenotypes (chemotaxonomy). Chemical screening has resulted in extensive chemotaxonomic databanks based on, for example, analysis of the protein, carbohydrate and lipid components of crops and foods. Recent developments in instrumentation have established high performance liquid chromatography (HPLC) as a particularly versatile and adaptable technology for separating molecules on the basis of their physicochemical properties. In addition, immunochemical and nucleic acid methodologies for detection of compounds have been adapted to produce easy-to-use kits (Skerritt and Appels 1995).

The combination of screening technologies with genetic engineering provides extremely powerful tools for the exploitation of genetic resources for human benefit (see 10.1.4 and 10.2).

10.1.1.2 DNA technologies: genome mapping

Whereas chemical screening provides characterization at the level of the phenotype, molecular biological techniques achieve characterization at the level of the genotype. Techniques such as DNA fingerprinting are becoming major tools for analysing populations and for taxonomic-

decision-making. The PCR technology, described in Section 2.2, combined with electrophoretic analysis of DNA products, underlies current DNA fingerprinting techniques. Useful characteristics from new sources, recognized through screening, DNA fingerprinting or ethnobiology, can be bred into cultivated varieties. Unique combinations of characteristics can be incorporated into single individuals, the process being facilitated by the identification of molecular markers linked to the desired traits.

Different kinds of genetic material occurring in living organisms can be used for DNA sequence studies. Genetic material is found, for example, in the cytoplasm of prokaryotic organisms, and in the nucleus and organelles (e.g. mitochondria and chloroplasts) of eukaryotic organisms. The different potentials for analysis of these kinds of DNA are summarized in Section 2.2, Box 2.2-4, and examples involving data from nuclear, mitochondrial or chloroplast DNA are briefly presented below as case studies.

The variation in the DNA sequences of the alternative forms that occur among different individuals in a population (polymorphism) provides useful markers that can be exploited to map the relative location of chromosomal segments. These markers can be found in the coding and non-coding regions of chromosomal DNA (exons and introns respectively).

The distance between two markers on the same chromosome can be measured in terms of base pairs (physical mapping) or in terms of their frequency of recombination (genetic linkage mapping). The process of sperm and egg cell production (meiotic recombination) may result in the separation of two markers originally found on the same chromosome. Generally, the closer to each other these markers are, the smaller is the chance of their being separated in the process of recombination.

A feature of the use of DNA markers in genetic analyses is that several ways are now available for measuring the *differences* in DNA sequence between individuals (see Section 2.2). If these differences are found to represent alternatives at a single position in the genome, they are considered to define alleles in the same way that alternative products from wild type and mutant genes define alleles of that gene. Allelic differences between individuals can therefore be identified within a specified DNA segment at positions that do not necessarily code for a gene product. In principle, this means that variation among individuals can be detected without *a priori* knowledge of chemical or morphological phenotype, thus allowing much more precise characterization of phylogenetic relationships.

Biodiversity can make a contribution to agricultural practice only when that diversity can be catalogued in a meaningful way. Depending on their respective resolutions, genome mapping techniques have significant potential in biodiversity conservation, assessment and utilization. Until

recently, mapping mammalian genomes has been an extremely difficult and slow process. New techniques, many derived from the Human Genome Project (Szybalski 1993), have been developed specifically to accelerate the process of mapping chromosomes. In many species there are specific patterns of repetitive DNA sequences that can be used to provide markers for segregating chromosomes (in the same way that, in 1865, Mendel used the colour of peas as markers for segregation). These numerous arrays of sequences provide more 'characteristics' than are available by examining the phenotype alone. In addition PCR, in its various guises, generates new analytical probes rapidly, using small amounts of material. Fluorescent *in situ* hybridization can be used to confirm chromosome assignments (Lichter *et al.* 1990).

Together, this suite of powerful techniques can enormously reduce the time taken to map genes and chromosomes, and can be used to help isolate individual genes. Researchers in major international projects are currently attempting to map the genomes of pig, sheep and cow (Gellin & Chevalet 1994; Broad & Hill 1994; Fries *et al.* 1993; Beattie 1994), and of *Arabidopsis* (Bevan 1994). Underlying these approaches is the reasonable assumption that related, perhaps feral, animals and plants will display conservatism of genetic information in two ways – related sequence information (homology) and related gene order (synteny). This type of information in such species may then be more readily derived and used.

10.1.2 Biotechnology applications in biodiversity assessment and management

The use of biotechnology to characterize biological material, including herbarium and fossil samples, generates information that can be utilized in developing databases for systematic studies, and thus contributes to the inventory and management of national floras and faunas. Applying biotechnology to clarifying taxonomic and evolutionary relationships among groups of organisms allows:

- effective definition of taxa as management units;
- the evolutionary uniqueness of lineages to be used as a measure of their relative conservation value;
- relationships between cultivated plants and animals and their wild relatives to be used to identify possible sources of genetic material for domestic plant and animal improvement.

Taxic diversity is an important consideration in biodiversity assessments, and is dealt with in the GBA principally in Section 2. A simple example of the application of biotechnology to enhancing the knowledge base on evolution and systematics is presented in Box 10.1-1.

Box 10.1-1: Biotechnology applications enhance the knowledge base on evolution and systematics.

Example: Chase *et al.* (1993) examined variation in the chloroplast gene *rbcL* (ribulose-1,5-bisphosphate carboxylase large subunit) of 499 taxa encompassing all of the major flowering plant lineages. The results generally agreed with comparable morphological studies, and supported several major hypotheses such as the sister group status of flowering plants and Gnetales, and the isolated position of *Ceratophyllum* as a sister to all other flowering plants. The important new insight from this study was the identification of a major division within the flowering plants, not based on the monocotyledon versus dicotyledon disjunction, but correlated with pollen type (exclusive of *Ceratophyllum*). The major role of broad analyses like this is probably in hypothesis generation rather than testing.

Biotechnology provides a variety of applications for increasing our current understanding of the dynamics of biodiversity. Information on processes such as mating, derived from the use of genetic markers, is important for an understanding of how biodiversity is generated, structured and lost, the topic of Section 4.

Biotechnology can also be used to assess rapidly the effects of ecosystem disturbances on components of biodiversity and on biological processes. It thus generates information critical to the management of biodiversity, sustained utilization of resources and long-term ecosystem conservation (see Section 13). Simple examples of applications of biotechnology to management solutions in biodiversity conservation are presented in Box 10.1-2.

10.1.3 Increasing option values: providing the knowledge base for biodiversity culture and preservation

In addition to enhancing the resolution when measuring and monitoring biodiversity, biotechnology can play important roles in culturing and conserving biodiversity. The possibilities for biotechnology to find solutions for *in situ* restoration of balance in natural ecosystems are illustrated by the examples above and in 10.2.2.2.1 and 10.2.3. In *ex situ* situations, it also provides new opportunities. For living resource collections it has potential for more efficient culture of the samples themselves, and for refining the quality of a collection as a whole. Biotechnology is also the entire basis for a class of non-living collections, namely DNA libraries and sequence databases. Biotechnology therefore profoundly increases the *option values* of genetic resource collections.

10.1.3.1 Ex situ conservation

Genetic resources are the basis of agricultural development because they can provide an enormous pool of genetic adaptability which acts as a buffer against environmental change. Valuable genes are dispersed through local cultivars and wild relatives. Destruction of natural ecosystems and replacement of local varieties by imported ones have led to the loss of wild relatives and of land races.

As discussed in Section 3.1.4.2, the growing world population is today largely dependent on only a restricted number of improved, high-yielding varieties. Although increases in food production have been achieved, they have been at a very high cost since many heterogeneous local varieties have been lost forever. The value of primitive landraces rests in their ability to withstand conditions that would seriously damage many modern cultivars, and also to provide resources for attributes such as nutritional quality and resistance to disease, as well as those characteristics which, unrecognized at present, may some day be considered invaluable.

Largely because of degradation or loss of habitat, therefore, off-site (*ex situ*) conservation measures for species and the genetic resources they encompass is a critical component of biodiversity conservation strategies. Options and management systems to meet this need, through botanic gardens, zoos and germplasm banks for example, are described in Sections 8 and 10.4. They use a variety of techniques, including intensive husbandry, cold storage and tissue culture, to maintain the quality and diversity of their accessions. None of these techniques would fall within the narrower definition of biotechnology that has been adopted here.

One role for biotechnology in *ex situ* conservation derives from its potential for refining the quality of *ex situ* collections (Gustafson *et al.* 1993). Taxonomic classification of germplasm collections based on morphological or chemical phenotypes can be tentative and/or redundant, and there is often no direct relationship between phylogeny and phenotype. On the other hand, samples characterized on the basis of known DNA sequence rather than on phenotype may provide a more comprehensive coverage of existing diversity, and may also provide the means of avoiding duplication (redundancy) of germplasm collections.

10.1.3.2 Biotechnology-enhanced option values

Molecular markers provide a powerful approach for investigating the genetic basis of variation between different varieties and for manipulating complex genomes. For the estimation of genetic diversity of germplasms the profiles obtained by DNA fingerprinting are sufficiently powerful to characterize and distinguish between the genetic bases of cultivars and their wild relatives. Based on DNA fingerprints, selection can be made for the

Box 10.1-2: Applications of biotechnology may be critical to good management solutions for long-term community and population conservation.

Example 1: An important question in the active management of natural populations is whether interpopulation transfer of individuals is an appropriate way to augment populations with low diversity or few individuals. This question is especially relevant given the rate at which habitat fragmentation and destruction is reducing the number and size of populations of many species. The answer is largely dependent on the amount of genetic differentiation among source and target populations. The introduction of individuals with maladaptive genes may, for example, result in outbreeding depression (see Section 4.2).

Gibbs *et al.* (1994) addressed this management question for the black rat snake in southwestern Ontario, Canada, where it is currently known from only four geographically disjunct populations, one large and three small. RAPD markers (see Section 2.2) were used to assess genetic divergence between the large population and one of the smaller populations. High genetic similarities between populations were observed, indicating that the populations do not represent different genetic stocks, and that translocation of snakes from the large population to the smaller one may be a suitable management option.

In contrast, examination of interpopulation genetic structure of the uncommon and vulnerable ghost bat (*Macroderma gigas*) in northern Australia, based on mitochondrial DNA RFLP markers and sequencing (Section 2.2), indicates highly developed geographic genetic structure, with the presence of several fixed allelic differences among populations (Worthington Wilmer *et al.* 1994). This suggests that current populations have been effectively isolated for long periods, a conclusion supported by observations of strong site fidelity among females. In this case populations should be managed as independent genetic units.

Example 2: Different technologies have different resolving powers with respect to biodiversity assessment. A good example is provided by the analyses of genetic structure of green turtles (*Chelonia mydas*) from the Indian and western Pacific Oceans (Norman *et al.* 1994). In this case, intensive RFLP analysis of mitochondrial DNA (see Section 2.2, Box 2.2-4) revealed four genetic groups of turtles which could be viewed as units for management purposes. However sequence analysis of a 385 bp segment of the control region showed an eight-fold higher divergence, and the existence of ten distinct genetic groups.

incorporation of material in germplasm collections or for the elimination of repetitive profiles. For example, Beeching *et al.* (1993) reported the use of RFLP markers to assess the genetic diversity within a collection of cassava germplasm. Significant levels of polymorphism were revealed, and made it possible to construct dendrograms indicating the genetic diversity within the collection. RFLP and RAPD (see Section 2.2) markers were used to study the genetic variation within and between trembling aspen and bigtooth aspen (*Populus* spp.) (Liu and Furnier 1993). Compared with allozymes (see Section 2.2), molecular markers clearly generate more polymorphic and species-specific loci in aspen, and RAPDs provide a very powerful tool for fingerprinting aspen individuals.

Chloroplast DNA variation (see Section 2.2, Box 2.2-4) can readily be assayed using RFLPs. For example, among 33 taxa of the cabbage family Brassicaceae, two separate evolutionary lineages each of which contained taxa cultivated as crops were identified by Warwick and Black (1991). They also observed a high level of congruence between currently recognized crossing groups and clusters defined by phenetic analysis of the cpDNA data. Such correlations suggest that cpDNA data can be used in a predictive fashion to identify potential crossing groups among undomesticated taxa which would

facilitate the introduction of new genetic material into breeding programmes.

Within a species, chloroplast RFLPs have also been used to ascertain the domestication history of species already in cultivation, allowing rationalization of current breeding programmes and relocation of superior provenances. For example, the application of chloroplast DNA markers to the analysis of the domestication of *Acacia mangium* has helped to define the populations to be used in breeding programmes. The species occurs naturally in eastern Indonesia, Papua New Guinea and northeastern Australia, and is used for the pulp and paper industry. Although *A. mangium* was introduced into plantations less than 25 years ago, more than 200 000 hectares are already planted in Indonesia alone. More than 90% of the plantations are derived from a seed orchard in Sumatra, and records suggest that this stand was sourced primarily from a narrow southern part of the species area. Isozyme studies failed to reveal sufficient genetic variation for use in biodiversity assessments (Moran *et al.* 1989). In contrast, a survey of chloroplast RFLP variation in ten populations throughout the range of *A. mangium* indicated that eight types could be identified. One chloroplast DNA polymorphism was unique to the southern part of the natural range of the species, and is presently being used to determine the

Table 10.1-1: Genome size and sequence knowledge of some selected model organisms.

Organism	Genome size (Mb)	Percentage of genome sequenced ¹	5-year research goals 1993–98 ²
<i>Escherichia coli</i>	4.8	76.0	100% 1998
<i>Saccharomyces cerevisiae</i>	14.4	27.0	100% 1998

proportion of the Indonesian populations that originated from this region. Since field trials indicate that *A. mangium* from Papua New Guinea and Cape York is superior in volume growth to the accessions from southern populations, the DNA marker will provide a critical indicator for accessions to be included in a breeding programme (G.F. Moran, pers. comm.).

Approaches based on DNA and RNA sequences may be especially valuable in microbial collections (see 10.1.3.3.2).

10.1.3.3 DNA libraries and sequence data

The ability to decipher the biological information stored in DNA and correlate it with phenotypic traits is to a large extent synonymous with modern biotechnology. Given that an ultimate goal of biological research is to relate DNA to protein structure and function, and eventually to physiology, genome analysis projects aim at building databases containing information on nucleotide sequences of genes, genetic markers, and the function and chromosomal location of identified genes. The emerging biological paradigm is that of ‘all “genes” being known (in the sense of being resident in databases available electronically) and that the starting point of biological investigation will be theoretical... the reagents that the scientist uses will include a knowledge of the primary sequence of the organism, together with a list of all previous deductions from that sequence’ (Gilbert 1991).

Prerequisites for this paradigm are the availability of appropriate genetic maps and clones and of rapid sequencing technologies. The latter are essential given the size of genomes of most organisms (Table 10.1-1). Genetic maps allow the assignment of genes to specific chromosomal loci, the study of the interaction of genes located in different positions and the effects of this interaction on phenotypic characters. Physical maps

represent the position of DNA segments relative to a chromosomal landmark (low resolution mapping) or relative to the exact order of all contiguous segments in the chromosome (high resolution).

Complete genome analysis involves the construction of high-resolution physical maps and is well under way in some model organisms (Table 10.1-1). The construction of physical genome maps involves:

- purification of chromosomal DNA;
- cutting the DNA into fragments at specific sites;
- cloning the DNA fragments into vectors;
- establishing libraries of the clones;
- ordering the clones in their exact chromosomal sequence; and
- sequencing the nucleotides of all clones or of trait-related clones.

10.1.3.3.1 Role of DNA libraries and sequence data in biodiversity conservation. Storage in the form of sequence data, naked DNA, genomic and cDNA libraries and isolated chromosomes has distinct economic advantages as a complementary approach to conventional methods such as cryogenic storage of whole organisms, embryos, oocytes, semen, stem cells and stem lines. Although not a substitute for live collections, the rate of species extinction and the lack of resources to maintain the latter dictate alternative strategies permitting the conservation of genes for future utilization of potentially useful traits. The value of this approach is amply illustrated by the study of ancient DNA samples, preserved in fossil tissues of extinct organisms. The amplification of minuscule amounts of DNA degraded to fragments as small as 100–200

nucleotide base pairs long is achievable by PCR technology. Comparison of the DNA sequence of these fragments with present or past relatives of the extinct organism reveals evolutionary changes within the gene pool as a function of time. In other words, it provides a time clock for rates of speciation and/or extinction. Framing strategies aimed at limiting the erosion of biological diversity depends on this kind of knowledge, and gene banks are an essential element in the implementation of such strategies.

Another potential role of genomic banks is alleged to be the reconstruction of an extinct organism from DNA sequence data. Whilst this may be far-fetched on the basis of the complexity of interactions that influence gene expression, cell differentiation and development, it is perfectly feasible to 'reanimate' extinct traits by introducing them into new species (Pääbo 1993). It may, however, prove easier to reconstitute a virus if its complete nucleotide sequence is known. Smallpox virus is a case in point. This virus has been eliminated except for stocks in two highly contained facilities (Atlanta, USA and Moscow, Russian Federation). There is considerable controversy about the eradication of these remaining stocks. This would constitute the first deliberate elimination of a biological entity from the planet and would have a number of ethical ramifications. In addition, there are safety concerns about the possibility of synthesizing smallpox virus DNA (186 102 base pairs) from the published sequence data (Mahy *et al.* 1993).

10.1.3.3.2 Role of DNA libraries and sequence data in biodiversity assessment and utilization. Genetic variation is not always related to variation of morphological and chemical phenotype. Often the latter is controlled by the environment and is the quantitative expression of more than one gene. One of the significant findings of sequencing whole genomes is the discovery of genes that code for undetectable phenotypes and as such cannot be mapped by classical methods. Construction of physical maps of polymorphic regions and sequencing of parts only of the genome are advantageous in the study of genetic variation within populations and therefore particularly pertinent to assessing biodiversity (see Section 2.1).

On the other hand, physical mapping of multigenically controlled (quantitative) traits (e.g. drought tolerance, insect resistance, yield), or of several unrelated ones, is a much more effective way of selecting traits than relying on phenotypic characteristics, and therefore provides a powerful tool in the exploitation of germplasm. As mentioned earlier (10.1.3.1), taxonomic classification based on DNA and RNA sequence data provides new possibilities for establishing phylogenetic relationships. This is of particular value in the study of populations of micro-organisms where phenetics are of little use in species characterization. Nucleic acid sequencing, mainly of 5S,

16S and 23S rRNA, has been used successfully in prokaryote taxonomy, enabling species and even strain characterization (see, for example, Stackebrandt *et al.* 1991; Roller *et al.* 1992). Given the value of micro-organisms in ecological processes and as sources of high added value compounds, the accurate taxonomic classification of these life forms is very important.

The potential of rRNAs for delineating phylogenetic relationships and taxon identification has developed strongly over the last decade. The number of partial and full rRNA sequences available from the Ribosomal Database Project (RDP) is in the hundreds (see Section 8.9). The RDP supplies its users with rRNA data and software packages for various applications (Olsen *et al.* 1991).

10.1.4 Biotechnology as a tool for utilizing biodiversity for human benefit

The combination of chemical and DNA screening technologies with genetic engineering provides an extremely powerful tool for the exploitation of genetic resources. For example, medium chain fatty acids such as laurate accumulate in the seeds of tropical trees and are harvested for dietary and industrial purposes at the rate of at least a million tonnes annually. Knowledge that production of medium chain fatty acids is due to a specific protein (acyl carrier protein-BTE) has led to the cloning of the DNA of the gene coding for this protein from the Californian bay (*Umbellularia californica*). This gene can be introduced into an oilseed species and can increase the levels of laurate (Voelker *et al.* 1992).

Many people interpret 'biotechnology' in this very narrow sense of using genetic engineering for human benefit. It is the facet of biotechnology that is perceived to have the greatest economic implications, and the one that has the highest public profile. It is also the facet of biotechnology most strongly linked with ethical issues and concerns about biosafety, and is discussed in detail in the following chapter.

10.2 Applications of biotechnology for the utilization of biodiversity

As described in chapter 10.1, biotechnology can be utilized for the assessment and evaluation of the enormous diversity of plant, animal and microorganism species still inhabiting our planet. Studies on the role of biodiversity in maintaining ecological equilibria have shown that the simple fact of existence of many species inevitably gives them a value. For some, of course, this is the highest value that can be given at present.

As human population pressure continues to increase, we are experiencing a rapid acceleration in the rate of degradation of biodiversity. Increasing efforts for food and fibre production will impact on marginal lands and wilderness areas, increasing the level of ecological disturbance. For socioeconomic reasons, which among other things involve the globalization of economies and intensification of production systems, this impact will be greatest where population growth is greatest, in developing countries and largely in the tropics. Accordingly, it is logical that there be strong demands for scientific advances that will increase the incentive and capacity of countries to conserve their existing biological diversity, such as, for example:

- assessment of the resource values of tropical forests;
- utilization, in breeding, of the wild relatives of domesticated plants and animals;
- search for undocumented species and investigation of their economic potentials; and
- soil rehabilitation.

This is not an easy task. For most known species, we do not have the necessary knowledge base to formulate sound development programmes. Even if there were substantial

increases in research budgets and numbers of trained biologists, the use of classical techniques alone could not possibly provide the short-term solution to the problem.

Fortunately biotechnology is providing new tools to help us in this endeavour, and for developing countries in particular it will be important to pursue the development and implementation of these new molecular techniques. However, it will be important that biotechnologists work together with ecologists to assemble rapidly the basic knowledge needed for evaluation of the genetic resource potential of biodiversity. Having the capacity to manage their genetic resources will enable countries to produce novel products derived from their own biodiversity, generating new income sources needed for development as well as the conservation of the natural resources.

Apart from its contribution to understanding the intrinsic ecological value of biodiversity, biotechnology can therefore also add to its economic value. The ability to assess biodiversity in whole or in part at the molecular level, through techniques such as DNA sequence analysis and markers, expands the reservoir of genetic resources that can be tapped by biotechnology. The combination of biotechnology and the conventional technologies of breeding and screening, as shown in the range of examples presented below, can speed up processes and often achieve targets that would have been unattainable with the use of conventional methods alone.

10.2.1 The scope of biotechnology applications

Biotechnology can be utilized in a wide range of applications, as outlined in Box 10.2-1. Living organisms can be used as factories delivering a variety of products, or targeted to a variety of end uses. They can be harnessed for environmental remediation, and also for various industrial processes. Biotechnology can improve the product yield and/or the efficiency of such activities.

Although biotechnology is commonly identified with genetic engineering, it supports a more diverse array of applications. In some cases, for example, conventional breeding is still more convenient for domestic plant and animal improvement, but nevertheless the use of molecular techniques can dramatically accelerate the breeding process (marker assisted breeding, see 10.2.2.1).

Other approaches which can overcome interspecific barriers, mostly in plants, are *in vitro* culture techniques, including *in vitro* fertilization or pollination, embryo rescue, cell fusion and somatic hybridization (10.2.2.1). Micropropagation is often an efficient means of plant multiplication, avoiding long generation times. Furthermore *in vitro* culture can increase diversity by somaclonal variation or mutagenesis. Fermentation methodologies can be improved by adapting the media and selecting for better performing cells. Another application of

biotechnology is the development of disease diagnostic kits, based on enzymes, antibodies or DNA probes (10.2.2.1). Sophisticated separation instrumentation (such as HPLC and counter-current chromatography) for natural product utilization is routinely used in biotechnology.

Nevertheless, genetic engineering opens a new spectrum of possibilities, because it breaks barriers between species, genera, families and even kingdoms, making available the entire gene pool for crop or livestock improvement (10.2.2.2). Production of subunit or even synthetic vaccines (10.2.2.2) is now possible, offering tremendous improvements in efficacy and purity. Because of this broad spectrum of application for human benefit, there are many biodiversity-based rural and manufacturing industries for which biotechnology is key to improving production efficiency, product diversification and sustainability of output. Some examples are listed in Box 10.2-2.

When the values of biodiversity are considered, attention is often focused on higher plants and animals. Viruses, microorganisms (bacteria, fungi, miomaleae) and other more complex microscopic species are often overlooked. The biochemical versatility and diversity of bacteria and fungi in particular represents an enormous variety of genes that are still unknown. More and more useful gene functions are being discovered, particularly for environmental remediation and industrial processes (Box 10.2-1). The heat stable Taq polymerase, which has revolutionized biotechnology, also has a bacterial origin (*Thermus aquaticus*). The early successes in plant genetic engineering often involved bacterial genes: these have included an endotoxin gene from *Bacillus thuringiensis* for insect resistance, a herbicide (basta) resistance gene from *Streptomyces hygroscopicus*, and a ribonuclease gene from *Bacillus amyloliquefaciens* for male sterility. Microorganisms also provide numerous antimicrobial compounds. Clearly microbial diversity should be considered in conservation and assessment programmes.

10.2.2 Improving production and sustainability

A major aim of biotechnology is to improve production, quantitatively as well as qualitatively (e.g. increased nutritional value). Disease resistance and stress tolerance dramatically improve yields. Improvements depend on the introduction of new genes or the modification of endogenous genes. Chimaeric genes with enhanced or reduced expression can be constructed and tuned to specific cell types or developmental stages. Alternatively, by spontaneous or induced mutagenesis, desired new characteristics can be screened or selected. However, most improvement strategies at present utilize genes already existing in the available biodiversity gene pool, from closely related lines or wild relatives to distantly related

Box 10.2-1: Areas of application of biotechnology in biodiversity utilization.

Using transgenic animals, plants and micro-organisms as sources of

- *proteins and peptides*: structural and storage proteins; peptide hormones (insulin, growth hormones) and antibodies; all kinds of enzymes;
- *lipids and fatty acids*: animal and vegetable oils; essential oils;
- *carbohydrates*: cellulose, agar, pectin, chitin;
- *secondary metabolites*: diverse organic substances utilizable for example as pharmaceuticals, food additives and biopesticides.

Targeting plants/animals/micro-organisms to specific end uses. Genetic engineering, breeding and in vitro culture systems can be used to:

- *enhance agronomic performance*: yield, disease resistance, stress tolerance and more.

Improving environmental maintenance/rehabilitation, through:

- *identification of soil micro-organisms by fingerprinting*: determining the best combinations for soil rehabilitation (nitrogen-fixing bacteria, mycorrhizae, bacteria capable of degrading pollutants, etc.);
- *use of plants naturally capable of accumulating high doses of heavy metal ions*: e.g. cadmium, zinc;
- *engineering the key bacterial genes involved in pollutant degradation*: improved clean-up efficiency;
- *improving plant microbe symbiotic systems*: for waste water treatment (controlling water hyacinth, reeds, duckweed);
- *production of biosurfactants, bioplastics and other biodegradable products from micro-organisms*: improving production by modifying biosynthetic pathways.

Enhancing the efficiency of microorganisms in industrial processes, such as:

- *microbially-enhanced secondary recovery of oil from reservoirs*;
- *bioleaching*: microbiological extraction of metals from often low grade ores;
- *production of industrial enzymes*: for the food industry; and for a variety of other production processes;
- *production of endogenous products*: enhancement of microbial fermentation for production of, for example, antibiotics, alcohol and organic acids.

organisms. These features can be introduced mainly via breeding and genetic engineering.

10.2.2.1 Biotechnology-assisted breeding in crop plants
Biotechnology provides important new tools with which to enhance the breeding process. Because of the high variability of the DNA sequences that comprise the genome, specific fragments can be found that are linked to

a trait that is known only by its phenotype. Such **DNA markers** can be identified in the seedling stage, and are independent of tissue or environmental conditions. A procedure to quickly link a DNA marker to a phenotypic character is **bulk segregant analysis** (Michelmore *et al.* 1991). Two bulked DNA samples are generated by pooling individuals that are identical for a particular trait or genomic region but arbitrary at all unlinked regions. The

Box 10.2-2: Biotechnology in the service of industries.

Rural industries. These may use biotechnology in many ways, including identification, by fingerprinting, of varieties and wild relatives; creation of new varieties or races using modified endogenous genes or genes from wild relatives or from other organisms through marker-assisted breeding, genetic engineering or *in vitro* techniques; gene manipulation for increased yields, improved nutritional value, disease resistance or stress tolerance; disease diagnosis by use of DNA markers, antibodies or enzyme assays; subunit vaccines; etc. in:

- *Agriculture*: especially for crop varieties and domestic animal breeds;
- *Forestry*: especially marker-assisted breeding for reduced generation time;
- *Aquaculture/mariculture*;
- *Horticulture, including production of ornamentals*: especially genetic engineering for qualities such as enhanced flavour and shelf life.

Manufacturing and processing industries. These industries generally make use of chemical compounds produced by plants, animals or micro-organisms (see Box 10.2-1: plants/animals as sources). Biotechnology can assist in: screening and extracting compounds of interest, as well as in enhancing the production of desired components via cultivation; *in vitro* cultures (cell-, root-, callus-, etc.); selection or screening of highly productive varieties (at cellular or whole organism level); mutagenesis; identification of important biosynthetic genes, cloning and production of derivatives from bacteria, yeast or plants, for:

- *Pharmaceuticals*: e.g. anti-cancer derivatives such as vinblastine and vincristine (from *Catharanthus roseus*) and taxol (from *Taxus brevifolia*); anti-malaria derivatives such as artemisinin (from *Artemisia annua*); subunit vaccines; antibiotics;
- *Cosmetics*: e.g. copaiva balsams and fragrances;
- *Food additives*: flavours, natural dyes, antioxidants; vitamins;
- *Energy*: e.g. carbohydrate fermentation for alcohol production; alternative biofuels such as *Jatropha* oil (*Jatropha curcas*);
- *Chemicals*, including: natural alternatives for biopesticides (e.g. pyrethrins from *Tanacetum cinerariifolium*; azadirachtin, a potent insecticide from neem); natural dyes (e.g. indigo, saffron, safflower); bioplastics, such as polyhydroxyalkanoic acids; biosurfactants, including oil derivatives such as soaps and detergents, surface coatings for paints, varnishes and printing inks, lubricants and hydraulic oils; linoleum;
- *Other manufacturing products*, including construction materials (e.g. timber, bamboo, rattan, teak, mahogany); textiles, ropes, paper (e.g. hemp, cotton, flax, jute); leather tanning.

Extractive industries. These utilize microbiological extraction of materials of low concentrations (Box 10.2-1), for example bioleaching, or materials recalcitrant to physical or chemical extraction (e.g. enhanced secondary recovery of oil). Biotechnology also has a potential role in the recycling of industrial residues (from pulping and paper manufacture, timber milling, fish processing, etc).

two bulks are therefore genetically similar in the selected region but seemingly heterozygous at all other regions. The pools are then screened for differences at the DNA level. DNA markers that are polymorphic between the pools will be genetically linked to the loci determining the trait used to construct the pools. Once a linked DNA marker has been identified it is a straightforward procedure to follow the selected trait through the successive generations and thus to develop the high-quality strain with the desired

combinations of traits ('marker assisted breeding'). When combined with methods of enhancing flowering and thus seed setting, the effort and time required to obtain commercially available breeds is dramatically reduced.

10.2.2.1.1 Molecular markers for rapid selection. To produce new varieties, desirable genes have to be incorporated and/or undesirable genes eliminated or replaced. If a domesticated race is being crossed with a wild relative this almost always results in the incorporation

of large numbers of undesirable genes along with the few desired ones. Several further rounds of crossing and selection are then necessary to eliminate these undesirable genes. Selection is often the rate-limiting step in improvement, mainly because the breeders depend on observing the final products of gene action and sometimes individuals have to be grown to maturity to select genes influencing the final product, such as yield. Genetic maps based on molecular markers present the breeder with a new set of tools to attack these traditional breeding problems. The maps consist of molecular markers that are distributed at fairly regular intervals over each of the chromosomes. Each gene will then of necessity be linked to one or more markers. By analysing segregation patterns of both the gene and the markers in the crosses, co-segregation can be used to determine which markers are linked to the gene. This indirect selection of the lines that contain new traits can be done on a large number of young individuals, reducing losses in time and expense compared to a traditional breeding programme where selections can only occur on the final product of the gene action. Marker-assisted selection is especially interesting for short-term breeding programmes, designed to develop new varieties quickly or to incorporate a new trait into an existing and otherwise desirable genotype. Detailed linkage maps saturated with RFLP markers are now available for several crops including tomato, maize, oilseed rape and sugarbeet (Bosemark 1993).

Marker-assisted breeding in forest trees presents a unique and interesting challenge, because inbreeding is generally not possible, multi-generation pedigrees are rare, generation times are long and resources are limited. The high heterogeneity that exists in most forest trees can be used to great advantage in mapping since it is a rich source of genetic diversity. Molecular marker maps based on RAPDs are available for various forest trees including *Populus*, *Eucalyptus*, white spruce and loblolly pine, and are currently being used as tools to identify and dissect Quantitative Trait Loci, in which the molecular basis is complex (Neale 1993; Kinlaw and Harry 1994). The advantages of the haploid genetics offered by conifer megagametophytes are also exploited for mapping work.

Crops can be protected against parasites and pests by cultural practices, application of biological control agents or pesticides, and the introduction of genetic resistance into the crop. However, breeding for genetic resistance has many advantages: the use of resistant cultivars reduces the pollution caused by pesticides, and even if the resistance does not protect the crop completely, partial resistance can lead to a marked reduction in the dose of pesticide required to provide satisfactory control. Moreover, a partially resistant crop will exert no (or only limited) selective pressure on the parasite. The sacrifice of a few plants can prevent the emergence of a new resistant parasite. Working

with a sufficiently heterogeneous population is necessary, since an inbred line can be completely destroyed when confronted with an adapted resistant parasite.

There are only a few drawbacks to resistance breeding. One important problem is that it takes a long time to introduce resistance into a crop. However, if genetic maps are available and markers co-segregating with the trait have been identified, screening for resistance can be done quickly at an early stage. Several programmes to identify co-segregating markers are in place, and different molecular markers linked to the Lr9 leaf rust resistance gene of wheat, the crown rust resistance gene Pc68 in oats and the rhm resistance gene to southern corn leaf blight in maize have been identified and localized (Schachermayr *et al.* 1994; Penner *et al.* 1993; Zaitlin *et al.* 1993). Resistance is often effective against only one parasite, and therefore the effort to introduce and maintain genes for resistance needs to be repeated for each cultivar and for each target parasite species. Additionally, the cultivar should not only be resistant but also produce a high-yielding good quality crop.

10.2.2.1.2 Techniques for wide crosses. Interspecific and intergeneric crosses have long been attempted by breeders in order to combine characteristics of different species. Unfortunately, interspecific pollination, *in vitro* or *in vivo*, frequently fails because the pollen tubes are incompatible with the pistil and stop growing before they reach the ovules. Thus the number of fertilized ovules obtained is very low, and when hybrid embryos do develop the failure of normal endosperm formation often leads to their degeneration. Embryos of such unsuccessful crosses can develop into normal hybrid plants on an artificial medium *in vitro* (endosperm replacement). The embryos can be rescued from the ovule several days after pollination, then followed by *in vitro* culture, or can be cultured *in vitro in ovulo* for a certain period after which the embryo is isolated.

These techniques have been practised for many wide crosses within both dicotyledons and monocotyledons (Foroughi-Wehr and Wenzel 1993). For example, red clover ($2n = 14$), an important forage legume, is normally of limited utility because of lack of persistence. Interspecific hybridization between red clover and *Trifolium alpestre* ($2n = 16$) using *in vitro* embryo rescue, results in a hybrid that resembles *T. alpestre* more strongly than the paternal parent, red clover. The hybrid exhibits the expected somatic chromosome number (15) and is functionally sterile in both male and female floral parts. This new hybrid combination may be useful for the future improvement of red clover if the infertility barrier can be overcome (Phillips *et al.* 1992).

As early as 1909, protoplast fusion was proposed as another possible way to produce new hybrid forms while eliminating all sexual barriers. No barriers exist to the fusion of cells of different species and families, but often

incompatibility reactions occur at various levels after the fusion, and the hybrids cannot regenerate or else give rise to highly abnormal and sterile organisms. These cell fusion products could not be introduced into breeding schemes, and led to the search for methods for transferring only part of a plant genome to allow the synthesis of partial but fertile hybrid plants. One of the solutions for chromosome elimination is the use of irradiated donor protoplasts, where the chromosomes are broken and the chromosomal fragments are transferred to the recipient genome after fusion. By this method Dudits *et al.* (1980) restored chlorophyll synthesis in a carrot albino mutant by fusion with irradiated parsley protoplasts. The production of these asymmetric nuclear hybrids between distant species allows sexually limited exchanges to be overcome, and offers many possibilities if polyploidy or the absence of fertile sexual organs, often the case in vegetatively propagated plants, is a restriction to gene exchange.

10.2.2.1.3 Disease screening. There is a significant deficit between realized and potential crop yields, and the losses due to parasites (pathogens and pests) are considerable. To prevent major losses it is important to detect and identify pests at an early stage. The development of molecular markers has introduced a new generation of diagnostic kits which can detect the invading parasite on the basis of its genetic material. This is in contrast to the immunoassay kits that detect the protein antigens that the invading organism produces. Molecular marker diagnostic kits, particularly for medical applications, are of much higher levels of sensitivity. Additionally, the creation of DNA primers that detect specific pathogens is both far more rapid and far more economical than immunological approaches.

Roosien *et al.* (1993) demonstrated that RAPD markers provide a basis for the development of a diagnostic assay to differentiate the potato cyst nematode species *Globodera rostochiensis* and *G. pallida*. Another highly sensitive PCR-based assay is used for the detection of plant viruses such as the potato virus Y and the fungus that causes blackleg disease on canola (Hataya *et al.* 1994; Landry *et al.* 1994). The claimed sensitivity of the test for blackleg disease is so high that as few as four spores of the fungus can be detected. It also differentiates between the aggressive and non-aggressive isolates, even in a mixture of DNAs. These levels of specificity and sensitivity allow the test to be performed on crude samples from seed, plants and stubble. For example, seed is simply boiled in a microwave oven and the DNA is extracted, incorporated in the assay and the result is available on the following day.

10.2.2.2 Genetic engineering

The most sophisticated way of improving domesticated species is through genetic engineering. This involves a DNA sequence of diverse origin (plant, animal or micro-

organism) being introduced into another genome, irrespective of how distantly the two are related. Notwithstanding its elegance, in the near future genetic engineering will not be able to provide universal solutions for the improvement of domesticated breeds and cultivars. The molecular basis of many agronomically and industrially important traits is often complex, owing to the number of gene loci involved (Quantitative Trait Loci). In such cases molecular-assisted breeding might be a more fruitful approach. However, there is still a considerable number of traits controlled by one or a few genes, and genetic engineering can be utilized, both for industrial and agronomic applications. For the key techniques see Box 10.2-3.

10.2.2.2.1 Applications of genetic engineering. The range of applications of genetic engineering is continuously extending. Very exciting new fields, for example, are industrial crop improvement and the development of a new class of vaccines. Now opportunities are arising, for example, in forest tree breeding, where long generation times mean that conventional breeding programmes are very slow.

The molecular basis of many agronomically and industrially important traits is often complex, depending on biochemical pathways with many steps, each regulated by one or more enzymes. As our knowledge of the genes that produce these enzymes increases, it is becoming possible to use genetic engineering to modify biosynthetic pathways. Genetic engineering is therefore no longer confined to the manipulation of single-gene traits such as disease or toxin resistance, but now also provides opportunities to change the nature and quality of many organic products. Some examples are presented below.

Because of the very high profile of genetic engineering in biotechnology, and its great potential for improvement of human well-being, the topic is further developed below under different headings. These relate to the variety of different outcomes that can be sought using genetic engineering; they may involve different techniques, and they commonly involve different biological processes and different target organisms. Examples involving both plants and animals are given.

Increasing productivity. Husbandry of domestic animals is a conservative practice, mostly using familiar animals in new combinations to generate new or modified phenotypes. This conservatism is a direct consequence of the large investment of money and effort required to generate new breeding lines. In the United Kingdom, for example, the principal bovine artificial insemination scheme uses semen from only a few hundred animals of superior pedigree. In aquaculture there is a greater willingness to embrace new organisms, perhaps related to the economic advantages of shorter reproductive cycles, but this is restricted in part by public acceptance. In all these systems, however, the desire for a consistent 'product' requires that the smallest number of parents is used to produce suitable breeding lines.

Box 10.2-3: Genetic engineering.

Key technologies. The main problems genetic engineering still has to cope with are the development of procedures to obtain fully transformed individuals, and the identification and characterization of genes of interest. Nevertheless, our capacity to genetically engineer living species is growing exponentially, and the research effort itself continues to grow. It is likely that gene transfer will become routine, and that for any newly discovered species or strains it will be possible to develop specific gene transfer protocols. This box briefly summarizes the technical basis of genetic engineering, using plants as the example.

Identification of the foreign DNA. In order to capitalize on our ability to transform plants, it is obviously necessary to identify and isolate the genes controlling the traits that are of interest to breeders. Some genes were originally isolated without their function being known, this being revealed only when the gene had been altered. In micro-organisms genes can be isolated easily by complementation of specific mutants. Often genes are isolated by using a homologue from another organism. A very interesting method of finding the gene that corresponds to a certain phenotypic trait is ‘chromosome walking’, which makes use of DNA marker based genomic maps.

Gene manipulation (e.g. regulation of gene expression). Many genes are not expressed continuously in the plant, but are turned on and off by other genes (promoters). There have been many advances in knowledge of the regulation of gene expression, and of the promoter sequences involved. By linking a novel gene to an appropriate promoter it is possible to specifically target the expression of the gene to a certain tissue (e.g. anther, root, xylem or seed) or even developmental stage (e.g. seedling). It is also possible to modify expression levels: by using or modifying specific promoters, the level of gene expression can be dramatically increased or decreased. It is also possible to knock out a certain gene, for instance by introducing an antisense orientated gene. The corresponding transcript is complementary to the normal one, and by hybridization translation is inhibited.

Transformation. The foreign DNA must be incorporated into the genome of the plant being engineered. Originally the crown gall microbe, *Agrobacterium*, was exploited for this purpose. This organism transfers some of its DNA to its host’s nuclei, thus performing a natural genetic engineering process. Subsequently various transfer procedures for naked DNA have been developed. These include polyethylene glycol treatment, electroporation and micro-injection as ways of bringing the foreign DNA to the target nuclei. Recently the most spectacular progress has been made through the development of microprojectile bombardment (DNA gun). Microscopic metal particles coated with the foreign DNA are ejected at high velocity to deliver the DNA into the plant cells.

Regeneration. The new or modified DNA (gene construct) is usually delivered to the nuclei of individual cells of the plant being engineered. It is therefore necessary to be able to regenerate fertile adult plants from these cells, using culture techniques. However, many important crops, such as legumes, cereals and commercial tree species are still very recalcitrant to regeneration. Some alternative procedures have been developed.

Regeneration alternatives. As well as exploring different means of DNA delivery, different tissues and cells have been used to avoid problems with regeneration. Although plant cells are generally considered to be totipotent and thus apparently easy to regenerate, this is often not the case. Tissues such as premature embryos, mature and germinating pollen, and apical, flower and anther meristem, which avoid *de novo* organogenesis, are more successful targets.

How might biodiversity and biotechnology interact to increase productivity of our farm animals? It seems likely that use of biodiversity as a resource for beneficial characteristics will be a slow process. This is largely because our understanding of physiological processes is in many cases inadequate: we often do not know which gene or protein is responsible for conferring the characteristic that we wish to modify or use in farm animals (see above). Our current understanding of reproduction, development, growth and feed conversion, the objective of much biotechnology, is founded on reductionist science. This approach, although essential for most research, does not lend itself well to alteration of organismal physiology or use of the full spectrum of biodiversity. Many of the approaches used to date focus

on clear targets, such as growth hormone (Pursel *et al.* 1989), for which defined effects have been obtained from protein studies. There are, nevertheless, some trends that indicate that our appreciation of physiological processes and our ability to map and to manipulate genomes will improve in concert.

Transgenic biology is founded on the identification, isolation and modification of genes (Box 10.2-3). Transgenesis currently uses only few genes at a time. However, different research groups have recently developed techniques for transferring large numbers of genes, using ‘cosmids’ (vectors that can carry 40 000 base-pairs of DNA) or yeast artificial chromosomes (‘YACs’, which can carry millions of base-pairs of DNA). Many research groups are actually trying to develop mammalian

artificial chromosomes (MACs) which could be used for direct transfer of large regions of DNA. Despite these opportunities it seems likely that, in the industrialized world, the farming community will continue to rely on the tried, the (partly) understood, and the familiar. Most approaches to alteration of productivity (growth rate, carcass composition, reproduction) will use genetically engineered constructs of single genes (perhaps modified *in vitro* to enhance the efficiency of their gene product). The expression of these genes may be enhanced (to increase or modify protein production) or targeted to an alternative site (Box 10.2-3).

Areas where the use of biodiversity appears to have a more immediate role are in stress tolerance and reproduction. The physiology of both these processes is poorly understood. However, the diversity of tolerance to environmental stress is a natural consequence of evolution, one that is often bred out of domesticated species in developed countries. Transfer of the appropriate gene(s) would lead to increased productivity, especially for animals on poor feed, but also for many farm animals in developed countries. The mapping procedures outlined above will be an essential part of this strategy.

Reproductive capacity, the ability to produce offspring that reach maturity, depends on a suite of factors from fertility to the quality of mothering. A small number of traits, such as the Booroola gene in sheep which predisposes towards twin births, have been identified, but the emphasis is on our current stock of domesticated species.

Over the next 10 to 20 years, the interaction of biodiversity and biotechnology is therefore likely to be neutral in its effects on animal productivity. The contribution that biodiversity in general can make is largely unknown because of insufficient information or because the information is not organized into an accessible form. Projects to formalize this information would be an important prerequisite for its use.

Direct productivity improvement in plants through genetic engineering is still a difficult task. However, some successes have been achieved indirectly. Hybrid vigour (heterosis), the remarkably higher vigour of hybrid varieties compared with both parent lines, is reflected in higher yield, increased resistance to disease, and enhanced performances in different environments (see Section 2.2). The production of hybrid seeds depends on the avoidance of self-pollination, which is often difficult to achieve. Through genetic engineering, a ribonuclease gene from *Bacillus amyloliquefaciens* was specifically expressed in the tapetum, disrupting this nutritive tissue essential for pollen development, and in this way male sterile plants were obtained which can only cross-pollinate.

Increasing environmental stress tolerance is another indirect way to increase productivity. Notwithstanding it being a complicated phenomenon, impressive progress has

been made and the first strategies for improving stress tolerance by genetic engineering have emerged. An example is oxidative stress. Reactive oxygen species play an important role in the damaging effects of many stress conditions. Over-expressing genes involved in reactive oxygen metabolism have already resulted in higher tolerance to cold, heat and ozone.

Controlling disease. Animals seek to minimize the effects of pathogens through many levels of defence mechanisms, from mechanical to molecular. In principle, modulation at any of these levels might result in improved disease resistance. Veterinary medicine in the West has always followed the approach of human therapy, laying emphasis on treatment rather than avoidance or prevention of diseases. Biotechnology, perhaps together with biodiversity, offers new opportunities to alter this balance. Natural and feral populations of relatives of our farmed animals often display different sensitivity to disease, and are a valuable resource of potentially important traits. Our increasing understanding of the roles of receptors for pathogens, of the immune system, and of cytokines is beginning to illuminate new possibilities for molecular intervention.

There are two main routes to disease resistance: to stimulate the host defence, for example by a vaccine, and to modify the host so that it is no longer susceptible, or at least less susceptible, to the pathogen. Either route could potentially make great use of biotechnology and biodiversity. Vaccines are being revolutionized by biotechnology, with methods being brought to bear on prevention of infectious diseases (Rabinovich *et al.* 1994). However, the majority of the searches for improved vaccines (more effective, more specific, safer) are being developed using components (genes or proteins) from known pathogens. The vectors for vaccine delivery will most likely be those that have been tested and found to be safe. Vaccination has also been proposed as a route for pest eradication, especially in Australia. Here the approach is to use immunocontraception, rendering the animals immune to gamete-associated antigens such as zona pellucida proteins or sperm proteins (Bradley 1994; Boyle 1994). Target species include the mouse, rabbit and fox. Clearly a requirement for such an immunocontraceptive vaccine is that they are entirely species-specific. There is considerable optimism that this is so, for the process of fertilization is itself a very species-specific event. In addition, some virus vectors are species-specific. However it will be necessary to confirm no reaction of, for example, a fox vaccine against domestic or feral dogs. Equally important, the release of a vaccine must be controlled to prevent spread of the vaccine to areas where the species is *not* a pest species (Tyndale-Biscoe 1994).

As mentioned above, disease resistance can be enhanced by intervention at any one of several stages of the

infectious cycle of the pathogen. Because each pathogen has a unique cycle, and because each response by the host is unique, it is normally not possible to generate general protocols for enhancing resistance. It truly is a case-by-case approach. However, there are many instances of quantitative differences in heritable disease resistance or tolerance (Freeman and Lindberg 1993; Klein 1993).

As described above, mapping and isolation of the genes encoding such traits should become a more rapid process using new technologies. In a similar vein, a useful catalogue of resistance to common diseases amongst domesticated and feral breeds would be an enormous, albeit an extremely useful, task. However, where the basis for resistance can be identified at the molecular level then there is the opportunity to use molecular methods as an initial screen of large numbers of breeds.

Crop protection is also a major objective in plant breeding, and most of the attention in genetic engineering has been directed to this area. Developing pathogen-resistant varieties is the ideal sustainable alternative for crop protection through toxic pesticides. Classical breeding for pathogen resistance may be very cumbersome as often the genes for resistance are not present in sexually compatible varieties. In the cases where only one or a few genes are mostly sufficient to obtain resistance, genetic engineering may be a preferable approach for conferring resistance to pathogens.

Different strategies have been developed for different pathogens. In many cases microbial genes have been used, but genes from wild relatives or distantly related plant (and animal) species are also good sources. Against insects the endotoxin gene from *Bacillus thuringiensis* has been engineered. For viral resistance, sequences of the virus itself have been introduced into the plant in order to interfere in the viral life cycle. Antimicrobial compounds from grasses, fungi (*Trichoderma*, *Aspergillus*), bacteria and animals (insects, rat, cow) are being used to obtain resistance against fungi and bacteria. Finally, finer tuning of endogenous, general resistance mechanisms in the crop of interest is another promising strategy for pest and disease resistance.

Improving product quality or novelty. As with changes in productivity, changes in quality or novelty are likely to come from classical breeding allied to the use of genetically modified genes. In the medium term, these genes will most often be selected from known sequences. The vast potential resource of biodiversity will remain largely untapped for some time. And, as with productivity, this lack of use largely reflects a lack of useful information.

Human blood and human tissues have been the raw materials for the preparation of many therapeutic compounds. With the development of transgenic biology, the spare synthetic capacity of the blood system or the mammary gland of farm animals is a viable alternative

means of producing these compounds (Carver *et al.* 1993; Swanson *et al.* 1992; Ebert *et al.* 1991). This novel means of producing biopharmaceuticals, sometimes called 'pharming', is likely to be a significant area of development and exploitation. It is also likely to involve the use of established breeds of animals using well-understood gene products. However, one important role of biodiversity, especially of plants, is as a well-spring of entirely novel therapeutics. Farm animals, used as bioreactors, can produce large quantities of 'foreign' protein. To use biotechnology in this way to synthesize such novel therapeutics will maximize the use of biodiversity while minimizing the use of the species of origin and consequently the possibility of driving them to extinction. As the efficiency of animals as bioreactors improves, and much improvement has already been seen, so their use becomes more scientifically, industrially and economically sound. It is likely that many medium-term changes in the quality of products derived from farm animals will follow the same pattern. Injection of growth hormone protein induces an increased ratio of lean:fat tissue in the carcasses of pigs (Machlin 1972). Transgenic animals containing a growth hormone gene show similar changes (Vize *et al.* 1988; Pursel *et al.* 1990; Wieghart *et al.* 1990). But these examples also demonstrate the inadequacy of our physiological subtlety: pigs subjected to either method of raising levels of growth hormone displayed health and welfare problems. It is likely that such problems will be overcome as our understanding of the natural processes increases and as the sophistication of gene constructs improves.

Most of the domestic species in industrialized countries have been carefully selected over centuries to maximize their productivity in domesticated circumstances. However, recently consumer-led demand for higher quality, more 'natural' products has led to an erosion of common farm practices and an increase in more 'natural' farming methods. In concert with this, some suppliers have emphasized the use of less domesticated or less popular breeds. It is not possible to predict the extent to which this trend will continue, but the available domestic breeds and indeed their less domesticated counterparts will be an important resource for future diversity through conventional breeding programmes and possibly through gene transfer.

Although the initial efforts in genetic engineering were directed mainly towards the improvement of agronomic crop performance, various industries have discovered the potential of this field for industrial crops. As described above (Box 10.2-1), plants can be utilized as chemical factories synthesizing a wide variety of useful compounds.

Although underlying biochemical pathways are often very complex, by changing the expression level of a single

gene or a few genes, the whole pathway can be reorientated. Starch, for instance, is increasingly the focus of material applications such as the production of biodegradable polymers. By modifying the activity of some key enzymes, starch types with different chemical composition are produced by the plant. Another example involves cellulose, the basis for paper production, which is associated with lignin in the walls of the xylem cells in wood. Research aims to engineer trees with partially reduced lignin content to reduce the difficulty and energy needs of the pulping process.

Plant oils, with their very wide range of applications (Box 10.2-2), are becoming an exciting domain for genetic engineering. In oilseeds, for example, it is possible to alter the proportions of unsaturated fatty acids, so that desirable fatty acids or oils will accumulate as the end product. Polyhydroxyalkanoic acids, which can be used as bioplastics, can be synthesized in oilseed rape by cloning into the latter the biosynthetic genes of these acids from the bacterium *Alcaligenes eutrophus*. New plants are being discovered or rediscovered, such as the African *Jatropha* which produces a good diesel substitute. Similar approaches can be followed to augment the synthesis of secondary metabolites.

10.2.3 Using biodiversity for environmental remediation

Biodiversity is the key resource for the rehabilitation and remediation of degraded and contaminated ecosystems. Biotechnology applications are of increasing importance to these efforts, enhancing both the specificity and the efficiency of remedial actions.

As is clearly evident world-wide, environments and ecosystems can be degraded through excessive modification, such as land clearing, and unsustainable exploitation for production. They can also be degraded in the sense that one type of land use may make them unsuitable for conversion to another type of use. Rehabilitation objectives may therefore involve the restoration and/or conservation of 'natural' ecosystems, or the maintenance of the original or altered production systems (see Section 13).

Some examples of biotechnology-driven management solutions for conservation objectives are presented in 10.1.2.2. Other examples, relating to production systems, include:

- genetic characterization of strains of ectomycorrhizal fungi which may be important as inoculants for reforestation of lands with a long history of intensive cropping;
- genetic characterization of rhizobia in situations where recovery plans for perennial native legumes are being developed; and

- use of DNA probes to screen soils for general changes in biotic composition resulting from land-use practices.

As is also clearly evident, environments and ecosystems can be degraded by excessive release of chemicals into them. A more specific and very significant aspect of environmental rehabilitation is the repair of such contaminated ecosystems. Further discussion below is confined to the utilization of microbial diversity for remediation of contaminated ecosystems.

Chemical contamination of our environment has been a highly visible and undesirable outcome of industrialization. Environmental clean-up is now a global issue, and has become a matter of global interest and action. Biological technologies for remediation, especially microbial ones, are often sought because they are usually less expensive than mechanical ones. This is because:

- bioremediation can often be carried out *in situ*, eliminating or greatly reducing costs for soil excavation and movement;
- the biological catalyst multiplies at the expense of the pollutant, thus naturally enhancing the remediation rate; and
- low cost resources are usually needed to implement the technology.

Bioremediation is therefore likely to become a preferred technology for clean-up of earlier wastes as well as to cleanse current waste streams. It utilizes the great diversity of organisms in nature and their catalytic enzymes, because it is this variation that results in the often novel biotransformation capacities. Considerable variation has evolved during nearly 4 billion years of microbial life on Earth, and it is this variation that provides the wide variety of transforming enzymes, tolerance to environmental stress conditions, and variety of respiratory processes that are key features for bioremediation.

10.2.3.1 Factors that limit bioremediation

Biodiversity promises solutions to a number of the factors that are limiting to bioremediation. These limitations are usually due to:

- the lack of any known organism with the capacity to transform a pollutant;
- environmental features that are limiting; or
- the absence of the appropriate organism at the particular pollutant site.

The lack of evidence of a biotransformation may simply mean that scientists have not looked extensively enough for the desired phenotype. It is likely that only a few per cent

of the microorganisms that exist in nature have been discovered, but if nature has not produced a gene for the desired transformation it is now feasible to consider constructing the desired protein by genetic engineering (Janssen and Schanstra 1994).

Environmental limitations to bioremediation include the following:

- The environment may be toxic owing to the presence, for example, of other contaminants, acidity, alkalinity or salts. However, microorganisms that can withstand these stresses are known, and some of the genes that confer tolerance to such stresses are also now known.
- Many of the soil and sediment environments containing pollutants are anaerobic. However, recent discoveries of new anaerobic biodegrading organisms suggest that some remediation may be achieved under anaerobic conditions.
- Some pollutants are tightly sorbed to soil, thus reducing their availability to organisms. Some microorganisms, however, produce surfactants that may be useful in enhancing the bioavailability of the pollutant to the degrading organism.

All of these improvements in bioremediation therefore rely on nature harbouring a great diversity of genes and organisms, and on the discovery of these organisms so that they can be utilized to overcome the potential limitations.

If effective biodegrading organisms exist, but are not present at the remediation site, then inoculation (bioaugmentation) with the desired organism can be attempted. Bioaugmentation can also be attempted with genetically engineered organisms. However, it is not easy to disperse inoculated organisms throughout a site because they are filtered out by soil and sediment particles (Harvey 1993). Some work has been done on selecting organisms modified in their adhesive properties to aid dispersal in aquifers.

The most easily managed bioremediation is when the pollutant serves as a growth substrate for the microbe, because selection will then naturally enhance both the degradation rate and dispersal. However, some of the newer, promising remediation technologies are based on co-metabolism of the pollutant, and not on growth. In this case the co-substrate must be supplied to stimulate the process. Genetic engineering offers the potential to recruit biochemical pathways from other organisms to convert some of these processes into energy-yielding pathways for growth. An alternative approach to improving co-metabolism processes is to engineer into the organism the capacity to grow on an environmentally friendly, cheap substrate that is rarely metabolized by the indigenous organisms (LaJoie *et al.* 1994). The co-metabolizing organism then can be more specifically stimulated to grow.

10.2.3.2 How can microbial diversity be discovered?

Discovering where new microbial diversity resides, and developing strategies to identify that diversity are equally important challenges, both for finding organisms and genes important to pollutant degradation and for the discovery of new pharmaceutical or industrial enzymes. It is known that most microbial species are very widely distributed on Earth, but that does not mean that particular phenotypic traits are equally universally distributed. One fundamental need is to understand better the geographic patterns of microbial diversity and how particular environmental conditions determine the indigenous microbial community. If many organisms important to bioremediation were rather uniformly distributed, then it could be assumed that microbes for bioremediation should already be present everywhere – including pollutant sites. Similarly, there would be less concern about ownership of such organisms by companies or countries since the same organism is likely to exist everywhere. A second major challenge in utilizing the large untapped reservoir of microbial diversity is the lack of appropriate strategies to detect and recover organisms with the desired features. Classical enrichment techniques have led to the isolation of many of the unique organisms that we now know, but this basic approach is 100 years old and does not lend itself to the recovery of all of the organisms of interest. New strategies such as using multidimensional gradients, the organism's positioning mechanisms, nucleic acid based tracking techniques, and new strategies of physical separation are being explored. Furthermore, methodology now exists to recover not the organism but its genes directly from community DNA extracted from nature, thus avoiding the need to cultivate fastidious organisms.

10.2.3.3 The classes of environmental contaminants

Tens of thousands of chemicals have been discarded into the environment by industrial society. Some present more serious problems than others because of their persistence, potential toxicity, and extent of environmental contamination. The most serious contaminants are described in Box 10.2-4.

10.2.3.4 Recent discoveries of diversity important for remediation

10.2.3.4.1 Anaerobic metabolism of BTEX. Microbes that can grow anaerobically on toluene, ethylbenzene and xylene using nitrate, ferric iron, and/or sulphate have been isolated, characterized and their physiological features determined. These are all members of newly discovered genera, illustrating the reservoir of diversity that has been found. Recently a microbial enrichment has been reported that can also grow anaerobically on benzene using ferric iron as the electron acceptor (Lovley *et al.* 1994). Together these findings show that the entire BTEX class of pollutants can be destroyed under anaerobic conditions.

Box 10.2-4: Serious environmental contaminants.

Chlorinated solvents. These include chemicals such as tetrachloroethene (PCE), trichloroethene (TCE), trichloroethane (TCA), and carbon tetrachloride (CCl₄) (McCarty 1993). These chemicals are water-soluble, and most do not serve as growth substrates. This class probably presents the most extensive and serious groundwater contamination problem.

Chlorinated aromatics. This group includes the polychlorinated biphenyls (PCBs), chlorinated dioxins, tetrachlorophenol (PCP), and chlorinated benzenes. The members of this group with higher molecular weights are strongly sorbed to soil and thus do not usually leach to groundwater, but they are also not easily biodegraded. Those with lower molecular weights are more leachable and somewhat more biodegradable.

Explosives and other nitroaromatics. This group includes TNT, RDX, and some industrially used chemicals such as nitrophenol. The reduction of the nitro- group occurs readily under anaerobic conditions. Complete degradation of the explosive members is not readily achieved under natural environmental conditions.

Polynuclear aromatic hydrocarbons (PAHs). This class includes chemicals with multiple aromatic rings, such as phenanthrene, pyrene and benzo[a]pyrene (Cerniglia 1993). These chemicals are strongly sorbed to soil, some are carcinogenic, and those with higher molecular weights are very difficult to biodegrade. Co-metabolism is the only known way to degrade those with higher molecular weights. These chemicals present some of the most widespread and serious pollution problems because of the extensive use of petroleum compounds and, historically, the casual means by which they have been disposed of.

Components of gasoline such as benzene, toluene, ethylbenzene and the xylenes (BTEX compounds). These chemicals are easily degraded by aerobic micro-organisms and, except for benzene, by some anaerobes. The chemicals are common groundwater pollutants because they are water-soluble and because of the widespread occurrence of spills and leaks. This is perhaps the easiest class of environmental contaminants to bioremediate. Bioventing and air sparging technologies are currently used clean-up technologies for vadose and saturated zones respectively (National Research Council 1993).

Metals. Heavy metals are perhaps the most difficult class of pollutant chemicals for which bioremediation may be useful. Some metals can be removed from waste streams by sorption of the metal onto the microbial biomass, and some metals can be oxidized or reduced by microbes which may alter their solubility. If so, solubilization and precipitation can be used for their removal. In both cases, however, the metal remains and must be appropriately managed for the long term, which is not the case for the organic pollutants that are mineralized.

Other chemicals. There is a variety of other pollutants, including pesticides, dyes, alcohols, ethers, ketones, creosote, glycols, nitrogen heterocyclics and organo-sulphur compounds, for which bioremediation is also a feasible technology.

This is a very important discovery because the greatest limitation to BTEX clean-up in nature is in the absence of sufficient oxygen at the site. Further understanding of these organisms, including their biochemistry, genetics and ecology, will be important for their effective use for one of the most extensive groundwater pollution problems.

10.2.3.4.2 Enhanced PCB degradation. New organisms with different PCB congener degrading capacities have been discovered, some in new taxonomic families not previously known to degrade these chemicals. Information from the molecular level is now revealing which genes confer specificity for the particular PCB congeners and in some cases it is known which amino acids alter the substrate range (Furukawa *et al.* 1993; Erickson and Mondello 1993). This information is critical to expanding the range of PCB congeners that can be degraded. Other work has led to the discovery of new chlorobenzoate degraders and to the isolation of their

genes, which if combined with the chlorobiphenyl degrading genes may lead to organisms that can actually grow on PCBs. To date no organism from nature has been found that grows well on the major congeners in the commercially used PCB mixtures. This is a case where genetic engineering for bioremediation may provide an important phenotype that so far has not been found in nature.

10.2.3.4.3 Niche adjustment to accommodate CCl₄. A new strain of *Pseudomonas* has been discovered with the novel property of hydrolysing CCl₄ without producing chloroform (Tatara *et al.* 1993). This process is known only for this particular organism, and when in a slightly alkaline environment (pH 8.2). This organism is now being tested in a biofence, which is a zone constructed perpendicular to the carbon tetrachloride plume and amended with the organism and the pH adjusted to 8.2. This provides a selective environment for the organism, and thus should stimulate the bioremediation process.

10.2.3.4.4 Chlororespiration. Several organisms have now been discovered that live by a completely different respiration process, using the dechlorination of a chlorinated substrate as the electron acceptor for energy generation and growth. This has been demonstrated for organisms grown on PCE, chlorinated benzoate and chlorinated phenol (Holliger and Schumacher 1995; Cole *et al.* 1994). Reductive dechlorination reactions have been found with PCBs and chlorobenzenes, but no organisms capable of respiratory growth on PCBs have yet been isolated, nor is it clear that the organisms that carry out the PCB dechlorination readily grow at the expense of this process. Nonetheless, reductive dechlorination, whether it be coupled to growth or not, is one of the most useful biodiversity discoveries for bioremediation in the last decade (Mohn and Tiedje 1992).

10.2.3.4.5 Co-metabolism of TCE. The great diversity of mono-oxygenases in microorganisms has resulted in some that have the capacity also to co-oxidize TCE. Organisms that grow on CH₄, NH₃, phenol and toluene are major examples (McCarty 1993). All these phenotypes have members that degrade TCE. However, not all organisms that grow on these substrates are equally active in TCE degradation, and some are completely inactive. Thus the biochemical diversity of these organisms is essential to this co-oxidation technology. The difficulty in implementing this technology arises from the uncertainty about whether active or inactive TCE degraders would be selected when the co-substrate is added. Gene probes are now being evaluated to determine whether they can be used to predict if an active TCE-degrading community is likely to be selected.

10.2.3.4.6 Construction of a TNT degrader. An organism that grows on TNT was recently constructed by taking from soil near an explosives factory an isolate that had the capacity to remove the nitro groups from TNT, and adding to that organism a plasmid that carries the ability to grow on toluene (Duque *et al.* 1993). The resulting organism could then grow on TNT. This illustrates what can be achieved by combining genotype features of two organisms that had existed under different selective conditions.

10.2.3.5 Traits sought in bioremediation

The more challenging bioremediation goals are not being met simply by inoculating a single organism that can complete the degradation. They may require either a consortium of organisms or the construction, by genetic engineering, of organisms with a combination of desirable traits. Consortia may be necessary to carry out different steps in the pathway of biodegradation, or they may be important because of the different phenotypic features maintained in the mixture, such as a range of kinetic

properties effective at different substrate concentrations, or tolerances to different conditions. Such mixtures are likely to yield more robust processes because of the diversity that exists in such communities. There is likely to be more interest in the future in not considering single organisms for bioremediation, but consortia.

Genetic engineering is an alternative approach which combines some of these different features into a single organism. The types of traits sought by genetic engineering are recruitment of pathways so that the pollutant becomes the growth substrate or so that the same organism can degrade more than one pollutant. This has been demonstrated for several chloroaromatic compounds (Rojo *et al.* 1987; Wackett *et al.* 1994). Alteration of the regulatory genes so that the pollutant induces the desired enzymatic activity or so that the pollutant-degrading activity is constitutive rather than inducible may be necessary. Genetic engineering also important to alter the active site to accommodate a broader substrate range or to enhance the rate of metabolism. It may also be used to effect microbial attachment or mobility, depending on whether the goal is to improve the performance of a fixed film reactor or to disperse the organism in an aquifer. Genetic engineering can also be used to enhance the surfactant-producing property of organisms and thereby potentially overcome bioavailability limitations (Finnerty 1994). Finally, genetic engineering can be used to make the organism more tolerant to co-contaminants, for example by introducing genes conferring resistance to heavy metals, tolerance to solvents or to pH extremes.

10.2.3.6 Tracking microbial strains added to the environment

Tracking the fate of a microbial strain added to the environment is essential in order to assess the organism's survival, growth and dispersal, and thus its effectiveness as a product, as well as to evaluate any unintended effects. Interest in the environmental impact of genetically engineered microorganisms has stimulated new tracking techniques. These include engineering the organisms with markers for easy detection such as the lac ZY gene for β -galactosidase activity; the lux and lac genes for light emission; selective markers for growth such as antibiotic resistance; detection of unique DNA segments by PCR; use of fluorescently labelled oligonucleotide probes to microscopically detect phylotypes by hybridization to ribosomes; and specific antibody-based methods such as ELISA. Each method has different advantages in specificity, sensitivity, cost and speed of applicability to particular organisms and environments. These methods have not yet been widely applied in bioremediation studies, probably because most studies have used indigenous organisms. The most sensitive, specific method for detecting added organisms without relying on their

cultivation has been the PCR-based method targeted at randomly cloned unique segments of the organisms' chromosome (e.g. Thiem *et al.* 1994). Methods based on probes or primers targeted at the variable region of 16S rRNA genes are also being used, but they are not uniquely specific for a single strain. Nonetheless, they are more convenient for studies on the population dynamics of the added organism and its competitors in the remediation habitat.

10.2.3.7 Bioremediation technologies

There are two basic classes of bioremediation technologies: intrinsic (non-engineered intervention to speed the process) and engineered (in which the process is enhanced by reducing the rate limiting parameter). To practise intrinsic remediation, considerable knowledge of the process and conditions controlling the process at the site must be known to ensure that the process continues at the expected rate. In engineered remediation, addition of oxygen, nutrients, surfactants, organisms and co-substrates are examples that are either in practice or have been tested in the field.

The bioremediation technologies in accepted commercial practice today are land farming, in which pollutant degradation is stimulated by the addition of nutrients and perhaps by oxygen from cultivation, and bioventing, in which air is drawn through the vadose zone of soil to stimulate the aerobic activities of the community. These are comparatively simple technologies which rely on the native populations of the soil community.

Several extremely promising emerging technologies are based on the discoveries mentioned above, although these technologies require more sophisticated knowledge and management. They include sequential anaerobic-aerobic treatment for remediation of PCBs; enhanced anaerobic reductive dechlorination of PCE and TCE; co-metabolic treatment of TCE, especially using phenol or toluene; and anaerobic biodegradation of BTEX. All of these technologies have now been demonstrated at least at the pilot scale in the field and would be expected to be more widely attempted in the near future. Another emerging technology is phytoremediation, in which plants are used as bioaccumulators of heavy metals to extract those metals from contaminated soils (Raskin *et al.* 1994). There have also been some studies in which the rhizosphere environment is thought to stimulate the biodegradation of organic pollutants in soil. In these strategies the plant's root system is used as a less expensive means of permeating the polluted site.

10.2.4 Roles of biotechnology in utilization of biodiversity: conclusions

Biotechnology provides important tools for biodiversity utilization for human benefit. Living organisms can be used as factories for specific products, targeted at a variety of

production end uses, harnessed for environmental remediation, or used in industrial processes. Biotechnology applications can serve rural, manufacturing and extractive activities.

Although not a universal solution, genetic engineering is the most elegant way of improving domesticated breeds or strains. Protocols for gene transfer are now becoming routine. Genetic engineering can be used, among other objectives, to increase productivity, control disease, eradicate pests, improve product quality or novelty, and rehabilitate a broad array of degraded or polluted ecosystems.

10.3 Impacts of biotechnology on biodiversity

The Convention on Biological Diversity, while recognizing the role of biotechnology in the attainment of its objectives [Article 8(g)], calls for measures to ‘regulate, manage or control the risks associated with the use and release of living modified organisms resulting from biotechnology which are likely to have adverse environmental impacts that could affect the conservation and sustainable use of biological diversity, taking also into account the risks to human health’. It also calls on the signatory countries ‘to consider the need for and modalities of a protocol setting out appropriate procedures, including, in particular, advance informed agreement, in the field of the safe transfer, handling and use of any living modified organism resulting from biotechnology that may have an adverse effect on the conservation and sustainable use of biological diversity’ [Article 19.3].

This chapter sets out to identify some of the potential adverse impacts on biodiversity arising from the use of recombinant technologies, and to present current approaches to environmental impact assessment and management. As pointed out above, however, it is important to note that such discussions do not imply that genetically engineered organisms are necessarily dangerous, or that non-engineered organisms are necessarily safe. The explosive generation of information in life sciences, and our increasing familiarization with the handling of transgenic organisms, changes continuously our perception of risk, and the adaptation of risk assessment and management procedures to the current levels of knowledge becomes quite a challenge.

10.3.1 Definitions of impacts

Loss of species and habitat diversity as a result of environmental introductions of genetically modified organisms (GMOs) is theoretically possible. Adverse biological effects on non-target populations and ecological and evolutionary disruption may be either the *direct* result of the introduced transgene(s) or alternatively the *indirect* result of changing socioeconomic conditions related to the application of recombinant technologies. At the same time, there are perceivable beneficial impacts on biodiversity. For example, the introduction of genetically modified microorganisms (GMMs) for bioremediation purposes, as described in 10.2.3, results in the addition of new genetic diversity for habitat restoration. Likewise, changing the reproductive behaviour of crop plants from sexual to asexual (apomixis) through genetic engineering may lead to significant economic advantages. Although the splicing of genes into organisms from unrelated species is thought to result in increasing genetic diversity, technology detractors would rather see this as increasing genetic ‘pollution’.

Whereas, in principle, direct impacts can be assessed by

scientific methodology and be tested experimentally, indirect impacts are by and large conjectural, being influenced by a multitude of intractable factors of an institutional, social and economic nature. The chapter addresses both as they form the basis of risk management considerations.

10.3.2 Direct impacts

Harm to biological diversity arising from the release of GMOs may result from the properties of transgenes themselves, or alternatively, from the transfer and expression of the transgene in non-target organisms. Disturbance of the dynamic population equilibria of ecosystems through GMO introductions may also result in adverse impacts on biodiversity. Enhanced ability of GMOs to invade natural habitats may lead to reduction of population diversity within species or – less likely – the displacement of an entire species, in cases where the latter is endangered or represented by only a few local populations (Edge 1994). However, it has to be stressed that the likelihood of this type of impact is highly speculative, and such concerns derive from earlier experience with introductions of ‘exotic’ natural organisms (10.3.2.1) which can not be considered directly analogous to introductions of GMOs.

In summary, the addition of a new genotype or species to a community can have various undesirable effects:

- displacement or destruction of indigenous species;
- exposure of species to new pathogenic or toxic agents;
- pollution of the gene pool;
- loss of species diversity;
- disruption of energy and nutrient cycling.

10.3.2.1 Lessons from past introductions

From the dawn of humankind the history of human travel is full of examples of the introduction of ‘exotic’ natural organisms into new locations. During the last 500 years colonists from Europe have brought with them many thousands of organisms as they visited and settled in ‘new’ lands. After colonization the importation of exotic species often continued for agricultural, recreational or pest control purposes (Drake and Mooney 1989). The last hundred years have witnessed many attempts (some successful, some not) to control pests by natural predators (see, for example, DeBach and Rosen 1991). How much can be learnt from these releases?

The considered view is that, using current methods for modelling ecosystems, we cannot reliably predict the outcome of the release of an exotic organism. Effects on population dynamics are extremely sensitive to environmental influences, and their manifestation is often slow to be recognized. The success of the rabbit

(*Oryctolagus cuniculus*) in colonizing Australia is often cited as an example of an introduction that had drastic and unforeseen consequences. The irony is that the rabbit, introduced into Australia 150 years ago, was not widespread in the United Kingdom until about 500 years ago. Introduced from its true natural home in Spain, several hundred years elapsed before its population increased dramatically during the fifteenth century (Thompson 1993). In a careful analysis of colonizations of Australia, New Zealand and the UK, Adam *et al.* (1993) pointed out that few of the outcomes could have been predicted: even subtle differences in behaviour, predation, reproduction, disease resistance and foraging between the exotic animal and the nearest natural counterpart can have far-reaching consequences. However, can we nevertheless make some predictions about the outcome of the release of transgenic organisms? Adam *et al.* (1993) argued that this will often be a more tractable problem.

The fundamental similarity of many transgenic animals to their parents is evoked in support of this argument. The modification is usually well characterized, and although pleiotropic effects in other genes must be considered, many of the effects of a specific modification can be assessed quite accurately. This argument might not hold for all modifications or for all species: both these variables are likely to become broader in coming years. For example, cold-tolerant and faster-growing transgenic fish have been produced. Would a cold-tolerant species displace a wider range of competitors? Would a faster growing or larger fish destroy more habitat or displace non-transgenic natives? One of the features of the assessment of a controlled release of transgenic carp in Alabama, USA, was the likely effects on ‘native’ carp (USDA 1990). The carp is an exotic species introduced to the USA from Asia in the late nineteenth century, and quite possibly displaced the natural fauna. Nevertheless the concerns are real, and in releases of this type it is critical that such concerns are addressed (Tiedje *et al.* 1989; Kapuscinski and Hallerman 1990). Ideally some biological containment (impaired reproduction, reduced stress tolerance) could be built into fish in aquaculture to limit their chance of propagating in the wild. It is also possible to conceive of, but difficult to engineer, systems of suicide genes, repressed in the true-breeding line, but which would be effective when heterozygotes are produced through mating with feral populations. If the transgenic organisms are designed to breed *inter se* and not with feral animals, then such systems should be a priority in development.

Our domesticated or cultured animals are often deemed to be less fit than their feral counterparts, and thus less likely to survive or spread widely. Whilst this is often true, it cannot be assumed *a priori*. It may be that a more rapidly growing goat may forage more widely and displace non-transgenic feral animals as well as destroy the habitat of other species.

Table 10.3-1: Some indicative attributes of importance for a successful invasion process (modified from Tomiuk and Loeschke 1993).

Vertebrates	Plants
Large econiche	Germination in a wide range of conditions
Large founder population	Many seeds, easy dispersal
Short generation time	Rapid growth
High genetic variability	Plastic perennials
Gregarious	Early flowering
Female able to colonize alone	Vegetative propagation
Larger than most relatives	Good competitors
Associated with humans	Associated with humans

Although some assessment of such behaviour could be made, a rigorous and complete examination is not possible. How rigorously should such an assessment be made? Should we treat transgenic animals more rigorously than we treat ‘exotic’ animals? In most cases, common sense and biological arguments would say no. Perhaps, then, the argument becomes one that we should apply the same rigour to all releases, but that the rigour can be tempered by familiarity and understanding of the genotype and phenotype of the non-natural species as well as of the receiving environment.

Table 10.3-1 lists some of the phenotypic attributes that are thought to enhance invasiveness. It needs to be stressed, however, that it is not necessary that all of these attributes occur simultaneously for a successful invasion. Consideration of the same attributes is instructive in the case of released GMOs as well.

10.3.2.2 *GMOs: invasiveness in natural habitats*

By analogy to the above, ecological disruption may occur from the addition of engineered phenotypic traits that are either toxic or pathogenic to non-target populations or increase the fitness of the GMO, thus rendering it competitively superior to the existing natural biota. Population size and the evolutionary properties of the introduced GMO are important parameters in the consideration of the effects that may result from such introductions as they may significantly influence the ecological dynamics.

For example, the high multiplication and mutation rates of engineered microorganisms may lead to the selection, accumulation and permanent or transient establishment of advantageous mutants in short time spans. More importantly, even competitively inferior mutants may eventually be established in areas where it is difficult to dislodge them (competition in structured habitats; Kim *et al.* 1991). A case in point is provided by GMMs used in

bioremediation and the utilization of toxins as growth substrates. The population of transgenic microorganisms may increase rapidly after their introduction (Lenski 1991). This effect, however, is likely to be mitigated by selection against the intended function of the transgene (e.g. depletion of the toxic substrate). A number of other mitigating factors are also known to operate (Table 10.3-2).

The rapid increase in numbers, and the establishment, of introduced GMMs may give rise to potential risks involving effects on biotic communities and known or predicted involvement in biogeochemical processes such as mineral cycling and nitrogen fixation.

Assessment of the potential risks is confounded by additional uncertainties arising from the speculative nature of the routes of transmission of the GMM (e.g. water, wind, air, biological vectors, mechanical means), its multiplication and survival potential, and the availability of appropriate econiches for establishment. In view of the intractability of these factors and the dearth of validated experimental models for quantifying most of the above-mentioned variables, work with transgenic microorganisms requires rigorous control measures (10.3.4.2).

The establishment of GMMs in the environment is intimately related to mode, scale and frequency of application. The potential ecological risks arising from the use of GMMs have been extensively reviewed in the literature (Stewart-Tull and Sussman 1992; Campbell 1991). However, it is argued (Lenski 1991) that engineering transgenes into microorganisms that have evolved to function optimally in a given econiche has the effect of ‘excess baggage’ on the GMM, which thus becomes less fit than its unmodified counterpart and, therefore, outcompeted in the presence of the latter. This argument may well hold true for higher organisms as well.

For plants, some applications of plant biotechnology have also generated concern as being potentially harmful to the environment. Invasiveness of transgenic plants is considered to be a perceivable risk, and an often quoted example is that of salt-tolerant rice escaping confinement and invading estuaries. Concern has also been expressed in

the case of engineered crops turning into weeds in agricultural and non-agricultural settings. Weediness is considered here in a broad context to include both persistence of plants in agricultural habitats and invasiveness in natural habitats. Even though the causes of weediness have been debated for many years, there is still no consensus on what characters contribute to making a successful weed. Because the performance of a plant species depends on interacting features of its environment and on competing plant species, it is not easy to make predictions on the likely weediness characteristics of particular transgenic plants (Tomiuk and Loeschke 1993).

The widespread use of transgenic plants in agriculture could enhance weediness in one of two ways. The transgenic crop plant may become more difficult to control in subsequent cropping (i.e. produce more persistent ‘volunteer’ plants), or the transgene may transfer to sexually compatible wild species and produce more persistent weed populations (10.3.2.3). The impact of both of these events will be determined by the nature of the transgene inserted and the receiving environment.

Herbicide resistance is often cited as a trait likely to produce more persistent weeds in agricultural habitats. This is likely to be the case only if there is no suitable alternative method of chemical or mechanical weed control. If several transgenes conferring resistance to different herbicides are introduced into a crop species, this could potentially contribute to the creation of a weed problem.

The effect of introducing other kinds of transgenes, such as disease resistance, pest resistance and environmental stress tolerance, would have to be considered as part of a risk assessment before field trials and commercialization of transgenic crop plants. However, plants in agricultural habitats are usually closely managed, and unless the transgene substantially increases persistence in agricultural habitats, transgenic plants are unlikely to have a significant impact on those agricultural habitats.

The impact of transgenes on the invasiveness of plants in natural habitats will again depend on the nature of the transgene and the receiving environment. Herbicide resistance is not likely to have any substantial effects on natural habitats because herbicides are not normally applied in those habitats, and therefore herbicide-resistant plants would not gain a selective advantage. Similarly, the effect of disease resistance, pest resistance and environmental stress tolerance will depend on the characteristics of the environment and on whether the transgene-carrying plants would be at a selective advantage. Transgenes conferring tolerance to stressful environments, such as saline soils, soils containing heavy metals or drought, could provide a significant selective advantage and this aspect would need to be considered in detail during the risk assessment exercise.

Generalized predictions of the likely impact of transgenic plants on persistence and invasiveness are not

Table 10.3-2: Summary of factors affecting hazard potential of GMMs (adapted from Strauss 1991).

Factors mitigating hazard potential	Factors enhancing hazard potential
Starvation	Increased fitness
Competition	Adaptation
Predation	Instability of transgene
Parasitism	Resistance/avoidance to predation
Unfavourable econiche	Favourable econiche

possible, and models based on the introduction of exotic species are not particularly helpful in this exercise (10.3.2.1). However, because of the long history of conventional plant breeding, it is important to draw on that experience in assessing the likely impact of transgenes on weediness. Where particular transgenes are considered likely to affect weediness, competition experiments may be helpful in assessing their likely impact. In the final analysis it may be necessary to monitor the impact of particular transgenic varieties during the early stages of their commercial use.

10.3.2.3 GMOs: gene transfer to non-target populations

Horizontal gene transfer of unmodified genes has been demonstrated in laboratory studies, and has been observed to occur in nature in the case of microorganisms (Médigue *et al.* 1991), albeit at variable frequency. By analogy, it would not be unreasonable to predict dissemination and establishment of a released transgene, under certain circumstances. With the exception of T-DNA transfer from *Agrobacterium tumefaciens* to plants, and of *E. coli* plasmids to yeast, however, fixation of prokaryotic genes in natural population of eukaryotes remains speculative (López-Pila and Scheler 1993). Knowledge of the method of transgenesis (if, for example, it is vector-mediated) and of the stability of the transgene in its host organism, is considered important in ascertaining its potential for being transferred into non-target organisms.

In the case of plants, the opportunity for genetic recombination between natural and engineered species, followed by successive breeding between the hybrid progeny and the natural species (introgression of transgenes), depends on the physical distance between the transgenic crop and the recipient species; whether flowering is synchronous; whether there is a means of transporting pollen from one plant to another (insect, wind, etc.), and whether the donor and recipient are sexually compatible. Once a hybrid forms, its fate will depend on whether the plant is able to develop vegetatively, and on its degree of fertility following self-pollination or outcrossing. The means of vegetative survival and propagation will also determine its success as a hybrid plant.

Sexual compatibility between crop plants and other plant species is the principal feature determining introgression. There are measures that can be used to prevent or reduce the amount of cross-pollination, such as isolation by distance, removal of flowers and use of male sterile transgenic plants (10.3.4.1), but once transgenic plants are in commercial production, reproductive isolation using these means is largely impractical.

Plant breeders have attempted wide hybridization for many decades as a means of introducing genes of agricultural importance into our crop plants. Because of this experience, there is a great deal of information on the

degree of sexual compatibility between our crop plants and their related species. Hybridization may occur easily, or may be extremely difficult and require ovary and embryo culture to rescue the hybrid embryo. Once a hybrid plant is formed its success then depends on its ability to survive and propagate in its current environment.

For an analysis of the likelihood of transgenes introgressing into natural plant populations, it is important to examine the evidence for introgression of genes from conventionally bred plant varieties into wild plant populations. Many of the characters currently manipulated by modern genetic modification methods fall into classes of characters that have been manipulated by conventional plant breeding for many decades. Most of the documented evidence to date, of introgression between crops and wild species, is between crop plants and related weed species. There is negligible information describing the extent and consequences of gene flow from crops to plants in natural populations. This may be because studies on natural populations are particularly difficult to carry out. However, if introgression into natural plant populations had made a significant impact on wild populations, it is reasonable to assume that an effect would have been observed. One of the main reasons why introgression between crops and plants in natural populations appears limited is that plants developed for agriculture do not often survive well in nature (reduced seed dormancy, reduced fruit shattering, poor competitive ability), so hybrids between crop plants and wild plants in natural populations are generally at a selective disadvantage.

As stated above, most of the documentation on gene flow is on introgression between conventionally bred crops and related weed species. Because the weed has to compete with the crop in an agricultural environment, introgression tends to lead to weed species that are genetically and phenotypically more like the crop. Gene flow has been observed between rice (*Oryza sativa*) and perennial rice (*O. perennis*), maize (*Zea mays*) and teosinte (various *Zea* species), sugarbeet (*Beta vulgaris*) and wild beet (*B. vulgaris* subsp. unknown) (Dale 1994). However, it is important to emphasize that even without introgression there is often a remarkable genetic capacity within many weed populations to adapt to agricultural conditions, and to become more successful weeds without genetic introgression. There are several well-documented cases in which weed species have mimicked the phenotype of crop plants without any evidence of genetic introgression (Dale 1994).

The consequence of genetic introgression between transgenic crop plants and related species depends on the nature of the transgene. A risk assessment needs to take into account the nature of the transgene, along with relevant features of the environment, before arriving at an estimate of the likely consequences of gene introgression. The environmental consequences of the transfer from

transgenic crops of transgenes conferring resistance to certain herbicides, resistance to stressful environments, or resistance to pests and pathogens, is being actively debated internationally. The consequence of the transfer of pest and disease resistance depends on the way in which sexually compatible wild relatives are influenced by those pests and pathogens. The introgression of genes conferring resistance to environmental stress will again depend on the characteristics of the particular environment to which the hybrid plant may be exposed.

A consideration of all these factors is a necessary feature of the risk assessment that must be carried out before experimental releases of transgenic plants, and before transgenic plant varieties are approved for commercial release. However, further studies on the extent of gene introgression between our crops and wild species would be helpful, as would monitoring of gene flow following the commercial release of transgenic plant varieties.

The issues discussed above are those that have received greatest attention in risk assessments to date and that are amenable to practical risk assessment. Other potential risks have been referred to in the literature as, for example, the impact of transgenic plants on soil microorganisms (Angle 1994; Morra 1994) and the potential of virus-resistant plants to broaden the host range of some viruses ('transcapsidation'; Rissler and Mellon 1993). However, our present level of understanding is inadequate to assess and evaluate these risks.

10.3.3 Risk assessment

The commercial development and environmental application of GMOs involves several stages of experimentation ranging from complete laboratory containment, through small-scale field trials, to large-scale production release. The purpose of experimentation is to test the alleged properties of the GMO under field conditions and its interaction with the environment of the release. Each stage involves extensive data collection on a number of phenotypic and ecological variables and their subsequent evaluation and statistical analysis. This gradual progression of experimentation and data collection is intended to build in adequate safety assurance regarding the potential impacts of the release on human health and the environment. It should be noted, however, that this step-by-step procedure is not always mandatory and depends on whether regulatory authorities deem necessary the collection of additional data for a more thorough assessment of potential ecological risk.

Assessing the risk associated with a particular process or event involving a GMO depends upon the *a priori* identification of the potential hazards, the estimation of their relative importance and the computation of the probability of adverse impacts. Points to consider in risk assessment include:

- Characterization of the host organism.
- Method of transgenesis.
- Characterization of the GMO.
- Intended use/effect of the GMO.
- Ecological relevance of the intended effect of the release.
- Monitoring, containment and control of the released GMO.

Although the ultimate objective of risk assessment is the quantification of the impact probability, in the case of biodiversity this is hardly feasible. Modelling approaches to help predict, for example, invasiveness of GMOs, range of pollen transfer, and the fate and effects of GMMs, are only approximations to real situations and need to be validated (Fiksel 1991). This is because the identification of potential hazards is confounded by the complexity of interactions of the introduced gene and the environment into which it has been released. Recognizing this difficulty, most regulatory review systems approach risk assessment on a case-by-case basis. Accordingly, individual applications for trialling or release of GMOs are assessed against criteria relevant to the particular situation of the release. Hazard identification and evaluation of the magnitude of the risk damage is based on the degree of knowledge (familiarity) of the GMO at hand and the environment into which it is to be released. Risk assessment also takes into account whether the application of management techniques (confinement and control of the GMO) could reduce the level of risk (UK Department of Environment 1993).

There is increasing confidence that, at least for some types of genetic modification and certain organisms, characterization of the phenotypic properties of the GMO and familiarity with the ecosystems of release allow reasonably accurate classification of risk levels (low, intermediate or high). Thus a generic *a priori* appraisal of risk is permissible. This departure from the case-by-case approach is becoming an evident trend in a number of regulatory systems (UK Department of Environment 1994; USDA 1993). It should be stressed, however, that risk evaluation is ecosystem-specific and therefore not necessarily valid in ecological settings where the GMO under consideration is likely to be confronted by different environmental variables.

There is also some concern that the step-by-step approach to risk assessment, involving the gradual reduction of GMO containment and increased geographical range of the release, contains some inherent methodological flaws. Small-scale field research of GMOs under the Good Development Principles (GDP;

OECD 1992) is designed to ensure minimization of potentially adverse effects on the site of the trial itself. GDP involves measures aimed at controlling and containing the GMO of interest (see below). This design feature raises questions about the predictive value of the data generated during the trial for environmental impact assessment arising from the large-scale release of the GMO. Reproductive isolation of transgenic crop varieties necessary in small-scale trials, for example, 'places a distinct limit on what can be learnt from release in terms of the effect on the environment beyond the vicinity of the test location' (OECD 1993).

In addition, small-scale field trials are designed to test the phenotypic expression of a gene of interest under variable environmental conditions and very seldom to derive data that are relevant to ascertaining the safety of a large-scale release (e.g. gene flow and dose exposure of other organisms to the GMO; Lesser and Maloney 1993). Indeed there is no statutory requirement for this type of data in most regulations pertaining to small-scale release of GMOs. There is, therefore, considerable need for more definition of the type and amount of experimental data to be collected during experimentation and post-release monitoring, as well as the time scale in which potential impacts are to be evaluated.

10.3.4 Measures for minimizing direct impacts

In field trials, the aim of these measures is to limit the possibility of gene transfer, exposure of non-target populations to toxic components expressed by the transgenic organism, and invasion of the latter into native ecosystems. Risk reduction is achieved mainly by confinement and control of the organism at hand, and is therefore attainable in small-scale field trials only.

10.3.4.1 Measures for transgenic crops

In the case of transgenic crop plants that have been transformed by means of biological vectors, it is possible to eliminate or disarm the vector and therefore the potential for vector-mediated gene transfer. It is also possible to delete the pathogenic sequences contained in some transformation vectors (e.g. *Agrobacterium tumefaciens* Ti plasmid) and to eliminate the possibility of their survival and transmission.

Dispersal of the transgenic plant beyond the test site can be controlled through reproductive isolation. This can be achieved by:

- Spatial separation of the transgenic plant from sexually compatible plant populations. The distance of separation may range from tens of metres to several kilometres depending on the reproductive characteristics of the crop species.
- Physical prevention of pollen movement (e.g. flower bagging prior to anthesis).

- Mechanical debilitation of reproductive potential. That is, removal of the male or female reproductive structures (e.g. detasselling), eliminating the chance of cross-pollination.
- Genetic debilitation of reproductive potential by the incorporation of male cytoplasmic sterility traits; by the incorporation of non-flowering traits (applicable where the plants are propagated vegetatively).
- Early or late induction of anthesis to limit cross-pollination with sexually compatible species.

For plants that have been transformed to contain a toxin, additional measures (isolation, caging) may be necessary to eliminate the possibility of non-target organisms (e.g. herbivorous insects) being exposed to the toxin.

10.3.4.2 Measures for genetically modified microorganisms

Unlike plants, genetic isolation of GMMs is not meaningful as the possibility of horizontal gene transfer cannot always be excluded (Vidarar and Stotzky 1992). Determination of the characteristics of the GMM and of the test site and surrounding environment are essential features of the experimental design. In view of the large number of parameters determining the multiplication, dispersal and establishment of viable organisms beyond the site of the experiment, as well as the complexity of interactions with other organisms and ecosystem processes, measures are aimed mainly at minimizing the dispersal of the transgene, or alternatively at preventing or mitigating its establishment beyond the test site.

In addition, it is possible to 'engineer' properties that minimize the probability of horizontal gene transfer and reduce the ability of the GMM to compete with native organisms. By definition, deliberate release of bacteria in the environment means the establishment of an adequate population to perform an intended function (degradation of xenobiotics, plant protection, vaccination, etc.). A useful strategy for containing bacterial establishment for the duration and the location of the intended use only is the integration into the genome of the microorganism of an environment-inducible gene that has the potential of killing its host if induced in an environment other than its intended use. This strategy is equivalent to the geographical confinement of the GMM. Several suicide systems have been identified in *E. coli* plasmids. The significant containment potential of this strategy is hampered by the fact that the total elimination of the GMM population is highly unlikely, either because of the possibility of mutations or through inadequate expression of the suicide gene (Molin 1993).

10.3.5 Indirect impacts

The direct effects of biotechnology on biodiversity operate through biological processes. The indirect effects are

predominantly socioeconomic ones, working through human economic and social systems. Yet because people live first within social systems, any indirect effects can be of major importance, especially for developing countries where many people rely directly on biodiversity for sustenance. Numerous examples are now emerging of potential beneficial socioeconomic outcomes. How these benefits may be identified and fostered is an essential component of the assessment of the use of any biotechnology application. On the other hand, negative implications exist as well, and should be considered in any assessment. As mentioned above, however, risk assessment relating to direct effects of biotechnology applications is distinct from that relating to indirect effects, and as a general matter should be undertaken independently.

Indirect effects can be defined as those operating through another mechanism. The potential number and type of indirect effects of biotechnology could be immense, and attempting to identify them all would be a speculative exercise of little practical value. The relevant mechanism of indirect effects to focus on is change in relative costs and prices. The effects themselves are the results of human responses to those changes.

As an example, biotechnology could lead to the identification of a plant material for an important pharmaceutical use. This use would raise the value of that material, which would increase collection pressures, possibly leading in poorly controlled areas to over-exploitation and species loss. Alternatively, biotechnology could simplify preservation technologies, increasing the chance that the species would be preserved *in situ*.

Indirect effects can be divided into *secondary* effects, those caused by the initial adjustments, and *tertiary* effects, encompassing subsequent adjustments. As a hypothetical example, biotechnology that replaced a broad-spectrum synthetic pesticide with a more specific and less costly biopesticide would be expected to foster greater biodiversity of animal life in the area. This would be the secondary effect. However, as a consequence of lower costs, farmers might increase the area farmed, potentially degrading regional biodiversity, or alternatively they might reduce the land area farmed, with beneficial effects on biodiversity. These would be tertiary effects. Another example of a tertiary effect of biotechnology involves the production of pharmaceuticals. Better medicines have led to population increase which is linked with environmental degradation and biodiversity loss. However, because of their speculative nature, or because specific connections are unclear, tertiary effects receive limited attention.

There is at present very limited field experience with the products of biotechnology. In terms of the definition used in this Section, very few species altered by biotechnology

are currently in commercial use. Consequently most indirect impacts of biotechnology applications cannot be analysed directly but rather must be assessed from related past experiences. Of these, the Green Revolution is perhaps the most relevant. Owing to the nature of the data, what can be projected most clearly of change is its direction, less clearly its magnitude.

The economic values of biodiversity, and the social and environmental impacts of changes in these values, are the major focus of Section 12. Because biotechnology is, in essence, a set of tools used to achieve the same broad objectives in biodiversity utilization as conventional methods, all of the general considerations presented in Section 12 apply to biotechnology, and they are not discussed in detail here. The discussion below focuses only on specific attributes of biotechnology that may have indirect socioeconomic effects and impacts on biodiversity.

Furthermore, in the brief discussion that follows, attention is placed primarily on the components of biodiversity regarded as genetic resources. Indirect impacts of biotechnology applications will arise mainly through changes to these components. However, it is implicit that preserving this part of biodiversity will contribute to the conservation of the whole.

10.3.5.1 Increases in value of genetic resources generated by biotechnology applications

Several attributes of biotechnology are likely to raise the value of genetic resources as inputs. For example:

- Biotechnology makes gene transfer possible both within species and between unrelated species, increasing the utilization potential of genetic resources and hence their value.
- Biotechnology, in the form of bioassays, has reduced the time and cost of screening for pharmaceutical and other uses and increased the value of the underlying genetic resources.

For discussion of how such values may be estimated, see Section 12.

10.3.5.1.1 Implications of value increases. Value increases through applications of biotechnology can have several implications. Most of these are of a general nature, and are discussed in Sections 11 and 12. They include interest and conflict over ownership of genetic resources, the rates at which these resources should be utilized, intellectual property rights, and formulation of laws relating to access to the resources. There are, however, some aspects of value increases that apply to biotechnology applications in particular, and are briefly outlined below.

10.3.5.1.2 *Remoteness of incentives for conservation.*

The placement of a value on sustainable as opposed to destructive uses of genetic resources for biotechnology applications would be expected to increase conservation. The Merck/INBio arrangement (Reid *et al.* 1993) is a well-known example of such an agreement, but the consequences for conservation are not easily recognizable in the well-protected national reserves that are the sources of the resource materials (see Sections 12 and 13).

The benefits of such direct uses of genetic resources flow immediately to the protectors. Whether these concepts will apply to less tangible and more distant benefits of biotechnology applications is not evident at this stage. For many genetic resources the immediate benefit from collection fees is small, and any real return must await a protracted period of product development.

10.3.5.1.3 *Moral/ethical debates.* The rise in value of genetic resources associated with biotechnology has been cast into a moral and ethical framework. The debate is sufficiently broad that it is not possible at present to determine the overall implications. Even so, there is a distinct possibility that the debate and the responses to it will lead to delays and restrictions on the use of genetic resources which are the raw materials for biotechnology applications.

Because the inputs often are genetic resources, and the means of incorporation is biotechnology, there have been many calls for sharing the value of the final products. This is reflected in the 'fair and equitable sharing' clause in the Convention on Biological Diversity [Article 15.7], as well as in calls for new forms of intellectual property rights for genetic resources and in specific proposals like 'Farmers' Rights'. Not everyone would regard these predominantly monetary issues as ethical matters, but they are so for many people for whom economic equality is often considered a matter of equity. For further discussion, see Section 12.

Objections to particular uses of biotechnology are more clearly ethical in the conventional sense. The use of human genetic materials in other life forms provides one particular focus, and raises cultural as well as individual objections. More general is the concept of 'species integrity', the notion that species have an inherent right to exist as created. The concept lacks substantial scientific support (see Macer 1990). It is an emotional rather than a scientific issue, and surveys indicate only a slight plurality of support for bioengineering of animals (Macer 1990. Fig. 4-1; 1992, Tables 4-2, 5-3).

Overall, the majority of people world-wide seem to accept a pragmatic approach to biotechnology termed 'Interest Sensitive Speciesism'. While that position is likely to determine policy in the long term, minority views, many in opposition, can inhibit utilization of biotechnology applications in the interim.

10.3.5.2 *Biotechnology-generated increase in agricultural productivity*

Agriculture, including aquaculture and silviculture, is the major land use in the world, and the principal source of human environmental impact. Hence anything that biotechnology contributes to agricultural activities will have environmental impacts, including impacts on biodiversity. Productivity increases attributed to the Green Revolution have resulted in the same amount of food, feed and fibre being produced in the 1990s on about 40% less land than would have been required using 1960s technology. It is possible that biotechnology will have similar effects, although the reality will not be known for many years. Improvements in the feed conversion of animals (including fish) will reduce the amount of land required to support the production of meat, milk and eggs.

General outcomes, consistent with all types of productivity increase, include using less but better quality land, and reduced pressure for cultivating new land.

The driving forces are primarily economic. Higher-quality land has lower production costs. Reduced pressure for the clearing of new land for agriculture can have powerful conservation effects, but local economic factors will ultimately determine whether this happens (see Section 13).

10.3.5.2.1 *Replacement of traditional landraces.* Traditional crop varieties are the result of millenia of selection by farmers, and are a major source of genetic diversity in agriculture and of genetic resources for plant breeding (10.1.2.1). Much use of such landraces ended with the Green Revolution, when so-called improved varieties replaced the local varieties. For example, whereas Philippine farmers at one time used hundreds or even thousands of rice varieties, two varieties accounted for 90% of the area planted in one recent year (National Research Council 1993, Ch. 1; Friis-Hansen 1994). Further improvements in varieties as a result of biotechnology are feared to displace yet more traditional varieties, exacerbating the loss of biodiversity and increasing the vulnerability of genetically uniform crops. The extent of this potential problem and appropriate management solutions are not yet clear (see Sections 12 and 13).

10.3.5.2.2 *Disadvantaged groups.* In the context of the possible benefits of biotechnology, those who will be relative losers are seldom discussed. The legacy of the Green Revolution and other major changes in technology indicate that biotechnology will disadvantage some groups, particularly in marginal production areas. Declines in crop prices, owing to reduced production costs, will further marginalize fringe areas. If they have no alternative non-farming land-use opportunities, the poor tend to degrade their environment further. Thus, without specific remedial action, further selective degradation and consequent loss of

biodiversity can be anticipated. The extent cannot be predicted at this time, but must be considered in the context of the overall effects of biotechnology.

10.4 Conclusions

10.4.1 Biotechnology provides important tools for biodiversity assessment and monitoring

10.4.1.1 Key molecular technologies for biodiversity assessment and monitoring include screening methods for various classes of compounds, and DNA fingerprinting.

10.4.1.2 Applications of biotechnology can increase our understanding of biodiversity at several levels, ranging from the effects of habitat modification or population fragmentation on partitioning of genetic diversity, through definition of taxonomic boundaries, to understanding evolutionary relationships on a broad scale. It contributes to our understanding of processes that underlie patterns of biodiversity. In effect, biotechnology brings new levels of quality and refinement to inventorying and monitoring of the living world.

10.4.2 Biotechnology provides important tools for biodiversity conservation

10.4.2.1 *In situ*. Applications of biotechnology provide data critical for the best management solutions for species. They allow assessment of optimal or minimal population sizes for maintaining diversity, and best practices for augmenting wild populations through transfers from other wild populations or from captive breeding programmes.

10.4.2.2 *Ex situ*. Biotechnology contributes greatly to the quality and efficiency of *ex situ* conservation of biodiversity.

10.4.2.2.1 Biotechnology increases the quality of *ex situ* germplasm collections. Samples characterized on the basis of DNA sequence rather than on phenotype can provide better coverage of existing diversity, and can provide a means of avoiding redundancy.

10.4.2.2.2 Biotechnology is the entire basis for a class of non-living conserved collections, namely DNA libraries and sequence databases. It allows compact storage of large amounts of genetic information which are recoverable for conservation or utilization objectives.

10.4.3 Biotechnology provides important tools for biodiversity utilization for human benefit

Living organisms can be used as factories for specific products, targeted to a variety of production end uses, harnessed for environmental remediation, or used in industrial processes. Biotechnology applications can serve rural, manufacturing and extractive activities.

10.4.3.1 *Biotechnology-assisted breeding*. Especially

through use of genetic markers, biotechnology can both enhance and accelerate the breeding process.

10.4.3.2 *Genetic engineering*. Although not a universal solution, genetic engineering is the most elegant way of improving domesticated breeds. Protocols for gene transfer are now becoming routine. Genetic engineering can be used, among other objectives, to increase productivity, control disease, eradicate pests and improve product quality or novelty.

10.4.3.3 *Novel genes and gene products*. Biotechnology-based screening (bioprospecting) can increase our capacity to locate and benefit from useful genes and compounds in the biodiversity around us.

10.4.3.4 *Environmental remediation*. Biodiversity is the key resource for rehabilitating degraded ecosystems. Biotechnology greatly enhances both the specificity and efficiency of remedial actions.

10.4.4 Biotechnology can impact on biodiversity in various ways

These impacts can be direct or indirect. Both for human benefit and for environmental conservation, the outcomes can be positive or negative. Importantly, there are realistic ways of assessing potential impacts, and therefore of gaining maximum benefits from biotechnology applications. The benefits can be realized for both industrialized and non-industrialized peoples and places.

10.4.4.1 *Direct impacts of biotechnology are ecological or evolutionary, and can be assessed by scientific methodology and tested experimentally*. They could include introgression, weediness, pathogenicity, altered nutrient cycling and a range of responses in other species populations.

10.4.4.1.1 *Procedures exist in many countries for assessing the possible impact of release of genetically manipulated organisms*. In general, these adopt a case-by-case approach, although generic *a priori* risk appraisal is becoming acceptable in some situations. Step-by-step approaches to risk assessment may be of little predictive value for assessing the risk of commercial releases. Careful definition of data required during experimentation and post-release monitoring is necessary.

10.4.4.1.2 *Risk reduction is achieved mainly by confinement*. Measures for minimizing direct impacts on native ecosystems aim to impose specified limits on gene transfer, on exposure to toxic products and on direct invasion. Good containment possibilities exist, even for microorganisms. Past experience with release of conventionally bred varieties is often a good guide for best practice.

10.4.4.2 *Indirect impacts of biotechnology are predominantly socioeconomic*. They can be of major importance because of the way social systems drive our use of biotechnology and biodiversity. Risk assessment for indirect impacts should therefore be independent of that for direct impacts.

10.4.4.2.1 Biotechnology can increase the value of genetic resources. In absolute terms these values may be limited, but value changes may lead to indirect effects. These may include conflicts over ownership, including intellectual property; altered rates of utilization and therefore of resource conservation and environmental protection; and ethical debates on the acceptable scope of the biotechnology applications themselves.

10.4.4.2.2 When biotechnology results in increased agricultural productivity, both positive and negative impacts can be predicted. These include changed pressures for cultivating new land, replacement of traditional landraces, and marginalization of fringe production areas through price changes.

Biotechnology has great potential to generate benefits, both environmental and socioeconomic. It can enhance our understanding of biodiversity and our capacity to conserve, manage and utilize it. It can improve our production systems and the diversity of the amenities we desire. In general, however, its impacts on biodiversity may not be different in nature, but only in degree, from those of our traditional or conventional practices. These impacts may be direct ecological and evolutionary outcomes of biotechnology applications, or indirect, resulting from

altered socioeconomic circumstances. The Convention on Biological Diversity calls for appropriate safeguards to ensure safe applications of biotechnology. We have a growing capacity to assess likely impacts, and to make informed decisions both for conservation of biodiversity and for equitable sharing of the benefits of biotechnology.

EXECUTIVE SUMMARY

Humans depend on biological resources for food, energy, construction, medicine, inspiration, and much else besides. Indeed, biodiversity and humans have had a close and mutually supportive relationship for tens of thousands of years. The biological resources upon which people depend have the critical character of being renewable, at least when they are managed well; but biological resources that are abused can also become extinct. The way societies have managed their resources determines how much diversity survives and the way that societies manage biological diversity determines the productivity of important resources and ecological services.

Human activities have helped to create substantial genetic and species diversity, and have increased the diversity of biological communities in particular regions through resource management practices and through the domestication of plants and animals.

A number of traditional resource management practices have supported the maintenance of species and genetic diversity. Systems of shifting cultivation in Southeast Asia, for example, often left some portions of the land permanently out of the rotation as sacred groves. And within the cultivation rotation itself, high levels of species diversity have been maintained, because the fallow fields offer productive feeding grounds for many species of wildlife. Shifting cultivation systems that once covered much of the land surface of the Earth (except Australia) have had a profound influence on biodiversity, often leading to increases in those species that were of greatest interest to people.

Low-input agricultural systems have long been important sources and custodians of biodiversity. Farmers frequently grow mixtures of different crops adapted to different localities in order to reduce the risk of loss to pests or extreme weather. Farmers have also traditionally engaged in active breeding of local cultivars and livestock, building most of the genetic base of our modern intensive agricultural systems. These traditional biological technologies have now been supplemented by modern breeding techniques and the new 'biotechnologies' including tissue culture and genetic engineering. These techniques rearrange genetic diversity and create new plant and animal varieties.

Within any given region, the introduction of alien species may increase the species diversity in that region. However, species introductions can be a major cause of extinction of native species and the global effect of increased rates of species introduction is overwhelmingly a net loss of global species diversity. Species are introduced for many reasons, most of which relate to the human interest in providing species that are especially helpful to people, such as agricultural species; but humans also accidentally introduce species, such as rats on oceanic islands and zebra mussels in the North American Great Lakes. Nevertheless, within a given region, species introductions can increase diversity. For example, the diversity of domesticated species in temperate cities may exceed the natural species diversity in the region, and many islands, such as those of New Zealand, now contain more alien plant species than native species. Similarly, the mammalian fauna of Britain has been increased through the introduction of new mammal species, even as it was earlier reduced by human-induced extinctions.

Biotic impoverishment – the loss of the characteristic diversity of species, genes and biological communities in a region – is an almost inevitable consequence of the ways in which the human species has used and misused the environment in the course of its rise to dominance; the factors that have led to the expanding ecological niche of humans are indirect causes of the loss of biodiversity. One study suggests that humans today annually mobilize approximately 40% of the total primary production on land, a massive and pervasive co-option of resources that inevitably leads to significant impoverishment of the biota.

The underlying causes of loss of biodiversity stem from changes in attitudes toward nature; growth in human population and natural resource consumption; the impact of global trade; economic systems that fail to value the environment and its resources; and inequity in the ownership, management, and flow of benefits from both the use and conservation of biological resources.

Human impacts on all levels of biodiversity are closely interrelated. An introduction of a new gene into a population, for example, could change the competitive dominance of that species, causing the extinction of a competitor and changing the composition and processes in the biological community. Recognizing that these impacts

cannot be fully separated, it is still useful to assess the impacts humans are having or could have on each general level of biodiversity.

Humans have been a cause of species extinction for thousands of years, especially when they migrated into new habitats. Hunting of large mammals in the Americas and Australia is thought to have contributed to substantial extinctions of large mammals between 50 000 and 15 000 years ago, as humans first moved into these continents. During the past 400 years, some 486 animal and 654 plant species are recorded as having gone extinct.

Despite the long history of human impact, human activities are placing significantly more species at risk of extinction today than at any time in the past as a result of environmental changes affecting current population sizes, environmental carrying capacity, population density, the mean and variance in population growth rates, the genetic structure of populations and the size, number and distances of suitable habitat patches and local populations.

The current dominance of intensive agricultural production in much of the world, which relies on lower levels of varietal diversity, has led to a significant reduction in the genetic diversity of crops and livestock under active management. For example, some 27% of the over 1400 recorded breeds of animals are threatened with extinction.

Declines in indigenous breeds and varieties and their replacement by a few varieties has been less extensive in developing countries but is now accelerating. In India, for example, an estimated 50 000 local varieties of rice existed until recently. Today, a small number of varieties is grown on over 70% of the rice land and on 90% of land allocated to wheat. In one district, an estimated 95% of traditional rice varieties have been lost.

The introduction of any new crop, crop variety or micro-organism can have significant impacts on the genetic make-up of other species in the region, and potentially on the composition of surrounding biological communities. The nature of these potential impacts is independent of the technology used to produce the variety: gene flow from a traditionally bred crop variety could represent as great a threat as gene flow from a genetically engineered variety.

Human impacts on biological communities take two main forms: conversion from one type of community to

another; and modification of the conditions within a biological community. Worldwide, forest and woodland communities have decreased by about 15% in area since pre-agricultural times. Temperate forests are currently relatively stable in area, while tropical forests are rapidly decreasing in area; but even in the temperate forests, the increasing area of plantations means that much biodiversity is being lost even if the forest area remains relatively constant.

Since 1700, cropland has increased five-fold and since 1800, irrigated cropland has increased 24-fold. The area in grassland has remained roughly constant over the past 300 years, with loss through conversion to cropland being balanced by gain through deforestation. The area of grassland has decreased significantly in Europe, North America and Southeast Asia, but this has been compensated by increases in Latin America and tropical Africa.

Commercial agriculture has led to considerable marginalization of the landscape. Surface irrigation schemes, for example, transform the complex mosaic of micro-habitats into a uniform agricultural mosaic, favouring a few crop species and varieties while displacing numerous micro-habitats such as hedgerows, fallow fields, tree groves, riparian vegetation, and so forth.

The introduction of alien species is often responsible for the modification of conditions within a biological community. Introductions influence the genetic diversity of native species and may alter species composition by causing the extinction of other species, influencing the interactions between other species, and altering ecological processes such as water chemistry, nutrient cycling and soil structure.

The perception that biodiversity management is primarily an issue of isolating biodiversity from humanity is a very recent phenomenon and is scientifically unfounded. Traditionally, biodiversity has been conserved and utilized as an integral part of resource management. While active protection of biodiversity by governments has played and should continue to play an important role in biodiversity management, even more important will be steps to reintroduce or restore local and regional management practices that successfully integrate sound management of biological resources.

11.0 Introduction: conceptual framework

Humans depend on biological resources for food, energy, construction materials, medicine, inspiration, and much else besides. Further, biological resources have the critical character of being renewable, so with proper management they can be used sustainably. However, when the levels of human use of biological resources exceed their capacity for renewal, the diversity and productivity of the system in which they occur may be reduced. Ultimately, the way that societies manage their resources determines how much diversity survives. Societies vary in the extent to which they use external inputs in resource management, with some societies living at a very basic stage and others almost totally dependent on external inputs (especially of energy). This section reviews the history of human impacts on biodiversity, assesses the factors that govern the way human societies influence biodiversity, identifies gaps in knowledge, and speculates about future human impacts.

The history of human civilization is intricately associated with the evolution of artefacts – objects constructed by people from natural resources. Centuries of effort have resulted in an endless procession of technological innovations which transformed many terrestrial and aquatic ecosystems, leading in turn to profound – but usually unquantified – impacts on biological diversity.

As indicated by historical evidence, traditional activities related to agriculture, fishing and livestock husbandry sometimes had the quality of sustainability, but many traditional systems also carried with them the seeds of their own destruction. Over time, selection may have led to sustainable systems that were in the self-interest of the people involved, at least at their current level of population and technology. However, with recent technological advances, changing demographic profiles and the quest for a ‘better’ quality of life, biological resources became easy targets for over-exploitation, and at an unprecedented rate.

Modern tools and technologies, with their roots in the Industrial Revolution and their flowering after 1945, changed the relationship between people and resources in at least two fundamental ways: scale and intensity. In terms of impacts on ecosystems, a large number of technologies aimed at short-term gains have also had long-term effects which may not have been foreseen. While many of these technologies are more efficient than the earlier practices (in the sense of being able to support more people), their pattern, scale and intensity of use have led to profound and unpredicted consequences for biodiversity. For example, mechanized fishing trawlers, with satellite back-up and on-board processing units, have led to depletion of many fish stocks. Intensive agriculture with multiple cropping by artificial manipulation of the soil system and high input of chemicals has resulted in increased wastelands and waterlogged areas in many parts of the world. New technologies intensify open-cast mining resulting in large-

scale loss of cropland and subsoil water. Taken together, the full range of heavy industries, chemicals, fertilizers and power plants has had significant impacts on surface water, groundwater quality and biological resources. However, the last few decades have also been marked by the development of technological innovations that appear to be ‘biodiversity friendly’, ranging from bio-composters and wetland options for waste-water treatment to national systems of protected areas.

Many of the issues involving human impacts on biodiversity can be illuminated by considering energy flows – especially in the form of carbon – between systems and regions. Once humans began to use sources of energy from outside their own bodies, their relationship with biodiversity underwent a fundamental transformation. The use of fire gave people the potential to change environments in fundamental ways, including converting forests to grasslands. The much later use of fossil fuels – formed from once-living organisms – has led to further changes, including international trade which has the effect of enabling local resources to be harvested to feed a global market that has little information on the impact of its harvest.

While the benefits to humanity of the use of fossil fuels such as oil and gas have been enormous, their use has also entailed costs to biodiversity. Fossil fuels have enabled the world to become a global marketplace, so that local feedback is no longer a mediating force in over-exploitation of local ecosystems. Fossil fuels have also played a dominant role in the Industrial Revolution, which has led to greatly increased levels of consumption and an additional range of costs and benefits for biodiversity. And fossil fuels have led to various forms of pollution, again with a range of impacts on biodiversity. Since fossil fuels are non-renewable, at least at time-spans of interest to humans, they will not form a permanent part of human cultures. It is therefore important that their impacts on biological resources be minimized so that the renewable resources remain available to support human welfare.

Among the most significant human impacts on biodiversity has been the domestication of plants and animals, which began thousands of years ago. The controlled breeding of plants and animals procured a more reliable and expandable resource base than subsistence hunting and gathering, allowing humans to reduce substantially the space required for sustaining each individual. This, in turn, provided a secure basis for cultural advancement, from the establishment of the first major settlements to entire civilizations. In terms of biodiversity, the selective breeding of species, whether conscious or unconscious, also expanded the range of human impact from habitats and species to genes. The 40 or so species of animals that have been domesticated have often greatly increased their genetic diversity, range and populations due

to human management, as have the 100 or so main domesticated plant species and thousands of other plants selected for use as food, spice, medicine, decoration and construction. But the gains for these species, which have had their fates linked with human desires, typically have been at the expense of other species which people found less easy to mould to their vision of the desirable.

The historical landmarks of tool use, technology development, energy capture and domestication form the building blocks with which humans have had and continue to have impacts on biodiversity.

11.1 The history of human impact on biodiversity

11.1.1 Introduction

Our species is remarkable for the wide range of plant, animal and mineral resources we put to use. Humans feed on mushrooms and grass seeds, green leaves and fleshy fruit, ants and crabs, fish and frogs, snakes and monkeys, dolphins and elephants. We also use bacteria to ferment milk and fungi to produce antibiotics; crocodiles and snow leopards to furnish hides, and eucalyptus trees to furnish the pulp out of which are fashioned clothes and shoes; trees to provide wood and whales to provide tallow for lighting; snails and ostriches to provide shells and plumes for fashion, and herbs to produce drugs. So people have become increasingly interested in harvesting more kinds of microbes, plants and animals for some human use or other.

The human species is also remarkable for its complex nervous system, with enormous numbers of nerve and sensory cells making highly specific interconnections and permitting exceedingly flexible patterns of behaviour. Beginning around 2 million years ago, our ancestors took advantage of this flexibility to master the use of tools and other technology, such as fire. This mastery over technology has permitted species of our genus *Homo*, first *H. erectus* followed by *H. sapiens*, to spread all over the Earth, colonizing not only all of the land surface, but more recently penetrating the ocean depths and outer space. The expansion of human use of the planet's environmental regimes has been accompanied by an explosion of objects fabricated by humans. The accumulation and expansion of knowledge and experience has given rise to a spectacular series of new technological devices, ranging from ploughs and pulleys to clocks, guns, steam engines, internal combustion engines, radios, television sets, computers, nuclear weapons and communications satellites. In fact it is possible to see interesting parallels in the history of evolution of life, and of objects fabricated by humans (Gadgil 1993). Like living organisms, fabricated objects have over time become more and more complex and occupied a greater and greater range of environmental regimes. Their use has permitted humans to modify the biosphere profoundly – mobilizing an estimated 40% of its

terrestrial biological production to their own ends (Vitousek *et al.* 1986). In the process, humans have significantly affected the magnitude and distribution of biological diversity on the surface of the Earth. The purpose of this chapter is to point to the major historical processes involved, although there is little detailed understanding of how these processes have affected levels of biodiversity.

An excellent framework for tracing this history is furnished by di Castri's (1989) interpretation of historical driving forces, following the work of Fernand Braudel (1979a, b, c). Braudel's school of history links and relates the patterns of daily life with long term historical trends, thus embracing different scales of space and time. Table 11.1-1 is a summary of the historical forces driving human impact on biodiversity, indicating when these forces began: most have continued to the present.

Boyden (1992) proposes four ecological phases of human existence in which societies are classified according to how humans relate to the biosphere and to other humans: the hunter–gatherer phase, the farming phase, the urban phase and the modern high-energy phase. The distinctions between the phases are not always sharp, some societies may not fit easily into one of these categories, and they are not evolutionarily linear as some of these phases may coexist in some societies. A simplistic manner of framing cultural diversity and its complex and divergent evolution does not exist, but these phases provide a useful framework within which to assess the history of human impact on biodiversity.

11.1.2 The hunter–gatherer phase

The hunter–gatherer phase represents the only known lifestyle and economy known for many thousands of human generations. Some groups, although diminishing, still belong to this phase. Hunter–gatherers are usually nomadic and fit ecologically into their habitat in much the same way as other omnivorous species. An important discovery which interrupted this presumed harmony and may have had major ecological impact on the local environment was the deliberate use of fire for driving game and clearing forest. This activity produced major modifications in vegetation patterns and fauna distribution in some regions. The invention and use of spears, bows and arrows, harpoons and nets also must have affected the interrelationships between human beings and populations of other animal species as, indeed, must have the development of language and its use for communicating observations about the environment. The effects of culture on humans themselves in the hunter–gatherer phase included impacts on techniques of food-gathering, and especially of hunting. Nevertheless, with the exception of the use of fire in some situations, it is difficult to determine accurately the impacts on biodiversity of these changes.

Table 11.1-1: Human forces driving changes in biological diversity (modified after di Castri 1989).

Before 1500	
1.	Fire.
2.	Hunting and gathering.
3.	Domestication of plants and animals.
4.	Intensification of agriculture.
5.	Trade.
6.	Intensification of agriculture by ploughing.
7.	Offshore traffic and trade.
8.	Building up of large empires (e.g. Persian, Roman, Mongol), with considerable expansion of communication and transportation systems.
9.	Long-ranging wars and military expansion.
10.	Large-scale invasions of people, long-distance shipping trade.
11.	Establishment of ‘market economies’ (e.g. Venice).
1500 to 1800	
12.	Exploration, discovery and colonization by Europeans of other territories and continents (e.g. the ‘Colombian exchange’).
13.	Establishment of new market economies and crossroad places (e.g. Amsterdam, London) favouring the globalization of trade exchange.
14.	‘Revolution’ in food customs (e.g. increased use of tea, coffee, chocolate, rice, sugar, potatoes, maize, beef and lamb).
15.	Increased demand for products such as cotton, tobacco, wool, etc.
16.	International introductions of exotic species through activities of acclimatization societies, botanical gardens and zoos, and for agricultural, forestry, fishery or ornamental purposes.
17.	Large-scale emigrations.
Since 1800	
18.	Rapid improvement of transportation systems (roads, railways, navigation canals).
19.	Large-scale industrial production and emergence of multinational companies.
20.	Large engineering works for irrigation and hydropower.
21.	High input, chemicalized agriculture.
22.	Mechanized fisheries and forestry.
23.	World wars and displacement of human populations.
24.	Tropical deforestation and resettlement schemes.
25.	Afforestation of arid lands with exotic species.
26.	Increased urbanization and creation of habitats characterized by cosmopolitan species.
27.	International interdependence of markets.
28.	Release of genetically engineered organisms.

Mastery over tools and fire permitted hominids greatly to expand the range of plants and animals they could harvest and eat or put to a variety of other uses. It also facilitated their dispersal out of the original homeland of savannahs of East and South Africa. By one million years ago, *Homo erectus* populations had migrated out of Africa and reached the very different habitats of Europe, Java and China, undoubtedly learning to harvest a whole new range of biological resources. Fewer than 2000 individuals are

known of fossils that can be applied to the human family. With such a relatively spotty fossil record, considerable controversy surrounds their taxonomy – estimates of the number of species involved range from five up to 20 or so. At any rate, it is generally agreed among anthropologists that the first fully modern humans appeared about 90 000–100 000 years ago. They seem to have expanded rapidly over the Earth. By 50 000 years ago they had reached Australia, and undoubtedly covered most of

Eurasia as well (Cavalli-Sforza *et al.* 1993). They probably moved onto the North American continent across the Bering Straits at least 12 000 years before present (BP) and over the next several thousand years covered both North and South America. Last to be colonized by humans were the oceanic islands, Madagascar, Polynesia and New Zealand (Diamond 1991). The first humans to arrive on any land mass usually lived by hunting animals and gathering plants, though the first colonizers of New Zealand were gardeners, and of Antarctica members of industrial societies. The impacts of these first colonizers on the biodiversity of their new-found homes appear to have been quite negative, culminating in the extinction of a number of larger bird and mammalian species (Martin and Klein 1984).

On first colonizing a new locality, early humans were unlikely to have been in a position to estimate sustainable levels of harvests of any of the plants or animals that they used. Nor were humans likely to have been concerned initially with sustaining harvests since they were most likely part of a movement of people who were seeing the option of moving on to yet another area if the resource base became depleted (Gadgil 1987). Consider, for instance, the first colonizers of the Americas entering Alaska across the frozen Bering Straits. They would have run into a land without any human competitors, full of large mammals unaccustomed to being hunted by clever and well-organized bipeds with bows, arrows, spears and other hunting technology. Such prey populations are likely to have been hunted without any special restraint, leading to decline, and perhaps extinction in some cases (Ehrlich and Ehrlich 1981; Martin and Klein 1984). Subsequent colonizations by people with more advanced technology were also accompanied by further waves of over-exploitation. Thus European colonization of the Americas led to waves of overhunting or overfishing proceeding from east to west, on a continent that had already been subject to a wave of significant extinctions from the first invaders (Koppes 1988).

The impact on biodiversity of colonization by hunter-gatherers was especially negative on islands, specifically due to hunting of endemic species and, occasionally, by the introduction of alien species. In Madagascar, for instance, early colonization apparently led to the extinction of larger species of lemurs and of elephant birds, and in New Zealand to the extermination of flightless birds such as moas, a large duck, a giant coot and an enormous goose (Martin and Klein 1984; Diamond 1994).

It is widely accepted that early hunter-gatherers usually concentrated on species that yielded the most returns per unit of time or physical effort put in, or that involved minimal risk; modern hunter-gatherers do the same (e.g. Lee and Devore 1968; Coon 1971). Only when they could not fulfil their nutritional or other resource needs with the

most desirable of such species would they be expected to turn to others less desirable. Indeed, optimal foraging theory, the branch of ecological theory that addresses how animals garner resources, suggests that early hunter-gatherers would have arranged potential resource species in a sequence, implicitly grading them on the basis of returns per unit effort (or time, or risk), utilizing only as many at the top of the sequence as necessary to fulfil their total requirements (Smith 1983; Redford and Robinson 1987). Large flightless birds such as moas in New Zealand and large, easily-hunted mammals in continental areas are apt to have headed such a list, perhaps along with large fleshy fruits such as durian or jackfruit, while rats or grass seeds might lie lower down. In this way the hunter-gatherers would first harvest the most desirable items, shifting to less desirable ones only on exhaustion of the more desirable options.

Earlier sections have shown that populations of living organisms are renewable resources which can be harvested, within limits, without depleting them. It is then possible to use any plant or animal species sustainably without driving it to extinction. However, in Section 4 it was shown that populations of living organisms are components of complex biological communities, so that their population levels may change greatly not only in response to the harvesting of a particular species, but also in response to the dynamics of other prey, predator or parasitic species, their geographical distribution and abundance, as well as fluctuations in abiotic parameters of the environment, such as cyclones, long dry spells of weather or onset or withdrawal of ice ages. It is then impossible even for scientists to determine precise prescriptions of the levels of harvest of any biological population that would be fully sustainable (Ludwig *et al.* 1993). The early hunter-gatherers probably eventually arrived at workable solutions of how to sustain harvests only on the basis of long experience at exerting different levels of hunting and gathering effort and monitoring the resultant changes in the species population under harvest (Joshi and Gadgil 1991); they doubtless made many mistakes in the process.

While domestication of plants and animals has considerably reduced the significance of hunting-gathering for most modern societies (see below), forestry and fisheries are two sectors in which harvests of natural populations continue to play a major role in global trade. During the early centuries of global trade these resources were considered limitless. As suggested by optimal foraging theory, these were then exploited with harvesting effort concentrating on resources yielding the highest level of profit. As any such element neared exhaustion, exploitation concentrated on the next most profitable element. This process of sequential exploitation is evident in the search for wood for railway sleepers in ever more remote tracts of peninsular India, of mahoganies in West

Africa, or economic extinction of successive species of whales. As it became evident that these resources were not really limitless, a body of theory was developed on how to harvest them sustainably. Sustainable yield has, however, remained a myth given the very limited understanding of functioning of natural ecosystems and the lack of reliable data on the dynamics of natural populations (Ludwig *et al.* 1993). Thus even today there are two widely varying estimates of the number of minke whales: those who favour whaling estimate the target population at 80 000, while those who are opposed to it estimate it at 4000. Given these kinds of uncertainties it is evidently difficult to arrive at workable prescriptions for sustainable harvests. As commercial pressures are continually pushing for ever higher harvests it is no wonder that there are indeed continued trends of sequential exhaustion of forests and fisheries all over the Earth – whether it be Siberia and the Baltic Sea, or Brazil and the Pacific Ocean.

11.1.3 The farming phase

By about 15 000 to 10 000 years before present, *Homo sapiens* had colonized all the continents, other than Antarctica, and many islands as well. The last ice age had just withdrawn, bringing climate changes that induced shifts in vegetation zones, drastically changing levels of plant and animal populations on which humans depended. Thus, the withdrawal of glaciers resulted in a warmer, moister climate, leading to a switch from grasslands to forests and from dry to wet forests. This may have reduced the availability of large mammalian prey for humans, a species that is generally agreed to have originated on and was best adapted to the grasslands and savannahs, and may then have rendered the habitat less suitable for human occupation, resulting in a change in resource availability in many parts of the world, especially in the tropics and subtropics (Flannery 1973; Rindos 1984). It has been speculated that these changes may have prompted some people in southwestern Asia, southeastern Asia and middle America to bring plants and animals under domestication, where they were selectively bred to bring advantages to people. The domesticated forms were, in turn, fed by people and protected from other predators.

Another possible explanation is that farming began in a haphazard way at a time when the climate was especially favourable for hunting and gathering (Boyden 1992). An abundance of food may have permitted a more sedentary lifestyle and, under these circumstances, some may have experimented with propagating plants and improving the farming of animals. Initially, these domesticated sources of food would have formed only a small part of the diet.

The earliest evidence of agriculture based on the cultivation of seeds, notably wheat and barley, and the domestication of goats, sheep and cattle, is found in a broad

area known today as the Fertile Crescent, extending from Greece to a region about 2400 kilometres to the east and to the south of the Caspian Sea, as well as in the uplands flanking the valleys of the Tigris and Euphrates rivers (Baker 1970; Heiser 1973; Reed 1977). In southern Egypt people were collecting and grinding grain from barley nearly 18 000 years ago. Their tools included grinding stones, some mortars and pestles, and blades of sickles, presumably used for reaping barley and perhaps other grasses (Ucko *et al.* 1969; Boyden 1992). The first signs of seed agriculture with millet and pig-raising in northern China date from 7000–8000 BP. In the Americas, it seems likely that maize had been domesticated by 7000–8000 BP in the region of southern Mexico, Guatemala and Honduras. Squash, beans, avocados, gourds, pumpkins and chillies were also cultivated by 5000 BP. However, until about 5000 BP hunting and gathering remained the main source of food. In the coastal areas of Peru, squash, beans, chillies, peppers and cotton were grown by 7000 BP although fish was also an important source of nutrition in these parts. In the lowlands to the east of the Andes, manioc, sweet potato and arrowroot were farmed, and on the Andean plateaux the potato became established as the main crop around 3000 BP (Salaman 1949).

The development of domestication marked the beginning of an entirely new era in the interplay between human society and biological systems. As a consequence, human populations no longer fitted into their ecosystems in much the same way as other large omnivorous species. This transition to domestication has allowed humans deliberately and systematically to manipulate biological systems, landscapes and waterscapes for their own perceived advantage using a small sample of the world's biodiversity.

The domesticated species consist of a tiny subset of all known living organisms. A few thousand of the 250 000 described species of flowering plants are today under cultivation, while a few tens of the 4000 species of mammals, 9672 species of birds, 24 000 species of fish and 40 000 species of crustaceans, and about 20 out of 70 000 species of molluscs, five out of millions of species of insects and a few out of thousands of species of bacteria, are domesticated by humans (see Box 11.1-1). That is equivalent to about 1 in 10 000 living species. Moreover, this is a very biased sample, with most domesticated species coming from tropical and subtropical biomes, especially from the more disturbed, successional habitats. In addition, traditional and indigenous communities have domesticated many species that are not counted here (Frankel and Soulé 1981; Turner *et al.* 1990).

The change in subsistence behaviour also resulted in higher food yields from a given area of land than had been the case in hunter-gatherer systems. Thus, farming systems

Box 11.1-1: Domestication and the history of microbial diversity.

Humans have also unwittingly moulded the diversity of microbes which live as commensals or parasites of humans and their domesticated plants and livestock. In the Old World, when towns were first established 6000 years ago, these unprecedented concentrations of human hosts permitted the evolution of new strains of epidemic diseases such as smallpox and plague. Similarly corn, domesticated in Central America, first became the basis of intensive farming in the Illinois and Ohio river valleys around 1000 BP. Until then the human skeletons recovered by archaeological excavations showed few signs of disease. With the arrival of corn, the skeletons suddenly began to show many pathologies. The number of cavities in an average adult's mouth jumped from less than one to nearly seven; tuberculosis became established as an epidemic disease; half the population suffered from yaws or syphilis and two-thirds suffered from degenerative diseases of bones (Cohen and Armelagos 1984; Eaton *et al.* 1988). Conditions for the survival and evolution of such microbes have continually improved with increasing human densities and movements, but in recent times have deteriorated with advances in hygiene, immunization techniques and antibiotics. Part of microbial diversity has thereby been reduced (as with the elimination of smallpox) but the elimination of all of its laboratory cultures remains controversial. In general, the diversity of human pathogenic microbes appears unaffected by medical advances, with new organisms such as hypervariable strains of viruses like HIV continuing to appear on the scene.

could support much higher population densities of humans. Population densities of hunter-gatherer communities are estimated to have ranged from around 0.02 to 0.2 persons per square kilometre; in early farming societies they ranged from 25 to 1000 persons per km². It is even believed that a peasant farming system in southern China supported 7500 persons per km². It is worth noting, however, that generally the amount of food produced per hour of human effort in early farming societies was comparable to that of hunter-gatherers.

Farming techniques, such as hoeing, irrigation, and eventually ploughing and manuring, and the kinds of animals or plants that were used, varied around the world. All early farming activities consisted of redistributing plant and animal species in a given area by deliberately increasing the local concentrations of species of food value to humans and decreasing concentrations of species with

little or no food value. Furthermore, it is likely that shifting or slash-and-burn agriculture was initially used both for vegiculture and for seed culture. Shifting was unnecessary in the cultivation of wet rice and some other grain crops because a fresh supply of plant nutrients was provided each season through irrigation. Between 5000 and 4000 BP, the plough came into use in northern Europe and by the time of the Roman Empire, some regions practised alternating fields between spring- or winter-grown grain and fallow (the two-field system). After this time and until well into the nineteenth century, the fundamental characteristics of the farming of cereal crops remained basically unchanged. With regard to other kinds of crops, the most important developments in European farming before the nineteenth century were the introduction of maize (or 'corn') around 500 BP and of the potato about 420 BP.

Domestication also implies the 'creation' of new varieties and races. But as people began domesticating plants, more animals were also brought under domestication. Only a handful of species has dominated farming, especially in Western societies: three medium-sized herbivores (sheep, goat and pig), four larger herbivores (cattle, buffalo, horse and camel), two carnivores (cat and dog) and only two bird species (chicken and duck) (Clutton-Brock 1981). These animals are maintained under two rather distinct systems: larger numbers associated with nomadic herding, or, in modern times, ranching; and smaller numbers associated with settled villages and cultivation (Grigg 1974).

A very different form of farming is *pastoralism* where nomadic people move with their flocks or herds of domestic ruminants over great distances. This is especially characteristic of arid and semi-arid areas. Nomadic herders, primarily dependent on cattle, horses, sheep and camels have ranged for millennia over large parts of Eurasia and Africa, moulding its biodiversity (the Native Americans of the Great Plains had a comparable relationship with a large wild herbivore, the bison, and migrated with the herds). From 8000 BP until five to six centuries ago, these formed largely autonomous warlike societies that kept agriculture out of the drier tracts of Eurasia. Consequently, the whole tract very likely remained under relatively light levels of grazing, with particular clans guarding their own pastures. They undoubtedly hunted extensively, but most probably had little adverse impact on the region's biodiversity. Rather, their major role, played so famously by Genghis Khan's golden hordes, was to promote systems of rapid transport over huge distances and create great trade routes such as the silk route between China and Arabia, thereby incidentally encouraging biological invasions.

In many parts of the world, commercial livestock production has taken the form of ranching, a system of agricultural production that originated in the second half of the nineteenth century. Beginning in the 1830s, ranching for sheep and cattle was established in Australia, on lands

until then used lightly by Australian aborigines for hunting and gathering. Since then, half the country has come to be grazed by domestic livestock (Holmes 1976). This expansion has caused ringbarking of trees and elimination of tree cover in New South Wales, Victoria and South Australia. In the drier tracts it has led to conversion of salt bush to grassland. In the process, a small proportion (less than 0.2%) of the plant species seem to have gone extinct (Wilson 1990). However, the process has caused an overall reduction in plant and bird diversity and lowering of population sizes of medium-sized marsupials (Friedel *et al.* 1990). Similar impacts have been felt in North America beginning around 1850 and in South America beginning around the turn of the century.

Humans have endeavoured, rather successfully, to acquire their growing biomass needs from intensifying the productivity of a small number of domesticated species. Populations of the favoured species have then reached high densities in limited areas manipulated as farmlands, pastures, fish ponds or plantations. Substantial quantities of biomass are exported from these limited areas, involving removal of large quantities of minerals from soil or waters. To sustain productivity, these minerals must be replenished, through a long fallow period when only a small proportion of land and waters are under intensive use, or through addition of manure or fertilizers. Fallowing was the technique originally followed in most places, and it remains a component of the shifting cultivation systems in many parts of Asia, Africa and Latin America today (Grigg 1974). Such a system of cultivating a plot of land for a few years and leaving it under fallow for a much longer period creates a mosaic of vegetation under different successional stages. Furthermore, part of the land was often left out of cultivation. Thus in northeast Indian states such as Manipur, as much as 10 to 30% of the land was permanently maintained under natural climax vegetation in the form of sacred groves (Hemam pers. comm.). Historically, this would have ensured the persistence of almost all the natural elements of biodiversity, coupled with stimulation of overall productivity by favouring faster growing early successional species in the patchwork of successional stages covering 70% to 90% of the land. Selection for adaptation to highly heterogeneous local environments accompanied by genetic drift would also have promoted considerable genetic variation in the cultivated species (Frankel and Soulé 1981).

It is now recognized that shifting cultivation systems also actively encouraged diversity in other ways. Recent work in the Amazon Basin has concentrated on longer-term changes in the forest structure, and has discovered practices that result in the creation, for example, of forest islands, or *apete*, by the Kayapo Indians of Brazil who live at the southern limit of the rain forest (Posey 1985). *Apete* begin as small mounds of vegetation about 2 m in diameter

(*apete-nu*). As planted crop and tree seedlings grow and the planted area expands, the taller vegetation in the centre of the mound is cut to allow in light. A full-grown *apete* has an architecture that creates zones that vary in shade and moisture. The species mix includes medicinal species, palms, and vines that produce drinking water. Of a total of 120 species found in ten *apete*, Posey (1985) estimated that 75% may have been planted.

New *apete* fields peak in crop production in 2–3 years, but some species continue to be productive for a longer period: sweet potatoes for 4–5 years, yams and taro for 5–6 years, papaya and banana for 5 years or more. Contrary to common belief, old fields (*ape-ti*) are not abandoned when the primary crop species disappear; they keep producing a range of useful products. They become forest patches in the savannah-like open *cerrado*, managed for fruit and nut trees, and ‘game farms’ which attract wildlife. This behaviour promotes patchiness and heterogeneity in the landscape through a number of devices. Posey first became aware that these isolated forest patches were human-made in the seventh year of his field research (Taylor 1988), but the local people were of course well aware of the dynamics involved.

Working in the Ecuadorian portion of the Amazon forest, Irvine (1989) has reported that Runa Indian swiddens resemble agroforestry systems rather than the slash-and-burn that merely results in temporary clearings in the forest canopy. Compared with unmanaged fallows, he found that management actually increased species diversity in 5-year-old fallows. Between 14 and 35% of this enhanced species diversity was attributed to direct planting and production of secondary species. Irvine (1989) characterized Runa agroforestry as a low-intensity succession management system which alters forest composition and structure in the long term.

Among the most diverse of agricultural systems known are the ‘home’ gardens in the humid tropics, the result of long historical development of technology designed to meet the needs of local agricultural communities. In West Java, the typical home garden appears as a crowded assemblage of trees, shrubs, climbers, herbs and creeping plants that are used for fruit, vegetables, starchy food crops, spices, ornamentals, medicines, fodder, fuel and building material, and involve over a hundred species. Even in the more arid regions, such as the Gondar area of northwestern Ethiopia, farmers plant together six or more crops, including maize, faba bean, sweet sorghum, cabbage, tomato, potato, pumpkin and bottle gourd. In northern Ethiopia, especially in the drought-prone areas, wheat and barley are grown in specific mixtures. In favourable years both wheat and barley give good yields, but in poor years barley still gives some returns.

In Vietnam, multiple varieties of early-maturing rice, *Oryza sativa* var. *indica*, are cultivated with multiple varieties of other *indica* and *japonica* rice with up to 20

cultivars harvested from one field. In Sierra Leone, in 1983 as many as 59 distinct rice varieties were planted by 98 households of one community, each farm averaging 4–8 varieties. The Kantu of Kalimantan, Indonesia, planted at least 44 varieties in one area with an average of 17 per household. A gene pool of potatoes of some 3000 varieties representing eight species are traditionally under cultivation in the Andes. In Papua New Guinea, as many as 5000 varieties of sweet potato are under cultivation, with as many as 20 varieties being planted in a single garden (Wood and Linne 1993).

This maintenance of considerable diversity of landraces in traditional farming is based on a great deal of deliberate effort since old varieties are continually lost due to outcrossing with other varieties or wild or weedy relatives of cultivated plants, and by a variety of chance events. So farmers historically have tended continually to acquire new varieties by exchange, through new encounters while travelling, through natural hybridization and from the markets. In Sierra Leone, new rice varieties are mostly borrowed from friends, while in Indonesia they are acquired as gifts as a new household emerges from an old one. In the Andes, some towns have a special reputation for the production of new varieties of potatoes from seed derived from outcrossing between cultivated species. The Aguaruna Jívaro from the Amazon Basin of Peru obtain new varieties of cassava through nurturing of volunteer cassava seedlings derived from accidental seeding. They also regularly exchange cassava varieties within the community as well as over long distances. Such patterns appear to be as old as agriculture and help explain the great biological diversity of traditional agricultural systems.

It is then entirely plausible that biological diversity was higher in earlier times, when large numbers of farmers of many different cultures had long-term stakes in the land they farmed and had control over their own technology. These historical systems of land management were highly variable, following a range of different rules to take into account specific attributes of the physical systems within which they were found, cultural views of the world, and the economic and political relationships that existed in the setting. Despite their great diversity, such systems often had characteristics such as clearly defined boundaries, specific rules on the harvesting of different products, involvement of the affected people in these collective choices, a system of monitoring the use of resources, cultural sanctions for those who violated the operational rules, inexpensive local mechanisms for resolving conflict, and ways of organizing these activities so that different types of decisions were taken at different levels. For example, Teran and Rasmussen (1995) found that pre-Colombian Maya agriculture was characterized by a high diversity of genetic resources and a similarly high diversity of agricultural and non-agricultural activities. In pre-

Colombian times all land was dedicated to mixed farming: land was communal, settlement was disbursed, and the system was supported by the ruling class. These factors resulted in higher productivity than is found today, where these conditions are absent. In addition, large tracts of the tremendously species-rich Amazonian forests that were viewed as virgin ecosystems until recently are now known to have been shaped by shifting cultivation systems of relatively dense populations of Amerindians. In fact, Denevan (1992) estimates that lowland South America supported over 8.6 million people prior to the European conquest – populations of both shifting cultivators and more permanent farmers that were greatly reduced by epidemic diseases brought in from Europe.

However, the highly diverse early farming systems generated very little surplus of production above and beyond the needs of the cultivators themselves; therefore they could only sustain autonomous, small-scale societies. The more complex agrarian and industrial societies that followed were based on large-scale resource exports from the countryside to the cities. Since shifting cultivation cannot provide such exports, more advanced agrarian, pastoral or industrial societies tended to generate them by conversion of the forest vegetation while restricting shifting cultivation to more and more circumscribed areas, usually in the uplands. Intervention of technologically simple societies by more advanced societies has also promoted growth in numbers of shifting cultivators. All of this has intensified shifting cultivation, shortened the fallow period, and often destroyed the sacred groves. Under these pressures tracts under shifting cultivation are today becoming progressively impoverished of biodiversity all over the world (Ramakrishnan 1992).

Erosion and chemicalization have been other causes of degradation in food-producing ecosystems. Although erosion is a natural phenomenon, overgrazing, unwise farming practices and the excessive use of wood have sometimes greatly increased the rate of erosion, especially in more ecologically vulnerable areas. As a result, fertile soil that has accumulated over thousands of years has been lost within a few years. Chemicalization occurs when there is an accumulation of unnatural concentrations of certain chemical compounds, which then interferes with plant growth. Boyden (1992) cites a historical example in which it is believed that excessive sodium chloride left in the soil following water evaporation was one of the main factors that caused the failure of the Mesopotamian agricultural system in the Euphrates and Tigris valleys, upon which the early Sumerian and Akkadian cities depended.

Apart from affecting the size of human populations and the lifestyles of individuals, one of the most obvious impacts of farming on biodiversity has been its influence on the redistribution of different kinds of plants, microbes and animals. For example, in Europe, the trees of the great

Figure 11.1-1: Regions of origin of domesticated plants and animals (from Boyden 1992).

forests that had covered much of the continent were displaced by Danubian farmers around 7000 BP. Until relatively recently many plant species used in farming systems, which had been domesticated at least 4000 years ago, were confined to their sources of origin (see Figure 11.1-1). In this context, the colonization of America by Europeans was especially important since not only were maize, potato, squash, gourds, pumpkins, peppers, chillies and the turkey introduced into Europe, but European cereal and vegetable crops, cattle, sheep and pigs were also introduced into the American continent. Eventually all the main European food sources were introduced to New Zealand and Australia. Just as new plants and animals were introduced into farming ecosystems, so were local native ones displaced.

The requirement of land for food production was not the only cause of deforestation. Eventually, the demands for timber for use as fuel and for various other purposes became increasingly important motives for felling trees. For example, although dense forest covered most of central and western Europe during Roman times, a significant increase in human population in the region is speculated to have caused ‘the great age of land clearance’ in the early

part of the second millennium. Paradoxically, it has been suggested that deforestation was also an important contributing factor in the decline of the Roman and Greek civilizations (Boyden 1992).

In another region, the Indian epic Mahabharata, probably based on events that took place at the junction of the Indus and Gangetic plains 3000 years ago, narrates the story of the destruction of the great Khandava forest on the banks of the river Yamuna near Delhi. Krishna and Arjuna, the two great warrior heroes of the pastorals, supposedly burned the entire forest driving back into the fire any creature attempting to flee the conflagration. Historical evidence suggests that the destruction of the Gangetic plains forest continued over the next five centuries and was nearly completed by the time of Buddha, 2500 years ago (Gadgil and Guha 1992).

Pastoralism has also led to significant changes in vegetation. The most significant of the domesticated animals (sheep, cattle, buffalo, horse and camel) feed primarily on grass and their maintenance has catalysed the conversion of much natural vegetation into grasslands all over the world (Stewart 1956). Fire has enhanced this conversion, and has promoted the spread of a small number

of grasses and other herbaceous species that thrive under fire. For example, the original vegetation of the Scottish Highlands was a forest cover of oak, pine, hazel, birch, alder and willows. This began to be destroyed during the Viking raids a thousand years ago, but was further reduced by exploitation for timber and smelting in the eighteenth and nineteenth centuries, and was nearly entirely eliminated to create pasturage for sheep. Initially this sheep-raising was immensely profitable, but over the past several decades it has been maintained only through government subsidies (Darling 1956). Similarly, most of the grasslands of India, dominated by a small number of grass species such as *Heteropogon contortus* and a few exotic weeds like *Parthenium*, have been created from much more species-rich tropical deciduous forests (Gadgil and Meher-Homji 1985). Large tracts of Central and South America have been converted to grass to graze beef cattle (Caufield 1984), and native American prairies have been largely eliminated by invading European species, even as the great herds of American buffalo have given way to European cattle (Crosby 1986).

The early farming phase covers the first known agricultural and horticultural systems to the high-energy phase of human societies where more recent developments have led to significant ecological changes in farming practices. From the first establishment of cities, the early farming phase has coexisted alongside the early urban phase.

11.1.4 The urban phase

The early urban phase includes all human populations living in cities from about two hundred generations ago, when some humans first began to live in cities, through to six or seven generations ago when the Industrial Revolution was under way in western Europe. These populations depended almost entirely on early farming communities for sustenance. Associated with this phase were important societal developments, including expanding growth in trade of manufactured goods and raw materials, increasing human migration and population, greater specialization and hierarchical stratification within societies, and the institutionalization of warfare.

Boulding (1973) has suggested that the two most significant phenomena of human history have been the tendency of our species to expand into an existing niche and our tendency to expand the niche itself once an old niche has become tight. Cowgill (1975), on the other hand, argues that population growth is not an inherent tendency of humans, but rather a possibility that is encouraged in some situations and discouraged in others. In his view, development followed perception and creation of new opportunities and new possibilities, probably more often by specific social segments or categories than by societies as a whole.

Over millennia people have continually broadened the

variety and quantity of plants, animals and minerals being treated as resources for human use. The distribution of these resources tends to be patchy, and people soon learned that trade could help them improve their way of life. These exchanges are ancient: archaeological evidence points to movements over long distances of stone tools fabricated in sites with especially suitable stone outcrops. New Guinea tribals too have for centuries exchanged shells from the sea coast for birds-of-paradise feathers from the interior (Rappaport 1984). Trade became especially important in agrarian societies with elites demanding goods, some of them valued simply because they came from a long distance away. Their possession was therefore a matter of prestige. Thus Indian ivory and peacock feathers were in great demand by the Roman nobility and rhinoceros horns were prized in the Chinese court, while Arabian horses were sought by Indian princes. Trade then became a very significant activity in the early urban societies, an activity that has had a growing impact on the Earth's biodiversity since it enabled even the most isolated groups to earn more benefits from biodiversity.

During the initial period of global trade there was little concern with conservation of biological resources, or of their diversity. Consequently, the newly-developed understanding of biological diversity was used for short-term economic utilization. A major component in this agenda was the screening of this diversity for its economic utility and the transfer of economically useful elements to other suitable regions on the earth. The botanic gardens, founded from the sixteenth century onwards in Europe, and more important the tropical botanic gardens established in the eighteenth and nineteenth centuries, played a key role in this process. Thus the botanic garden at Bogor, Indonesia, founded in 1819, was responsible for the introduction of the oil palm (*Elaeis guineensis*) in 1848; and those of Calcutta, India founded in 1787, and Peradeniya founded in 1821 and Gampaha 1876, both in Sri Lanka, played a significant role in the development of rubber plantations of Southeast Asia (indeed the latter garden was created especially to receive and grow rubber plant seedlings) (Heywood 1987). In such a fashion cocoa was transferred from South America to West Africa, potatoes from the Andes to Europe, nutmeg from the Moluccas to Grenada and coffee from Africa to Brazil and Colombia. The emphasis was on the creation of monocultures for intensive production of a small number of commercially valuable biological products. The inevitable result was large-scale local erosion of biological diversity (Grigg 1974).

The movement of people, often over very long distances, has also been significant in human and ecological history. Some of these migrations have been voluntary and peaceful; others have been violent and forced by dominant human groupings. The movements of Asians into the

Americas, Madagascar and the Pacific were discussed above. A more recent great and demographically significant movement consisted of the spread and expansion of Europeans to all corners of the globe. This began with the exploits of the navigational adventurers from Portugal, Spain, Britain, France and Holland in the late fifteenth and early sixteenth centuries and, in particular, with the European discovery of the American continent and, two centuries later, of Australia and New Zealand. Europeans began to settle in North America in the sixteenth century and in South America early in the seventeenth century. In Australia and New Zealand European settlement began in 1788 and 1790 respectively. In southern Africa the Dutch started to settle in 1632, and the English in 1788 (Crosby 1986).

In North America and Australia, Europeans largely displaced the local native populations. Their biological advantage was partly due to their technology and weaponry, but it was also the consequence of the fact that they introduced into the local populations a series of devastating infectious diseases – diseases to which they themselves were, for historical reasons, relatively resistant. In Mexico, for instance, smallpox wiped out at least half the local population in the first few years after initial European contact.

Associated with the voluntary migration of Europeans to the Americas was the involuntary migration of Africans to the same region as slaves. It has been estimated that between 1451 and 1870 about 11 million slaves were taken from Africa, of which 9.6 million were still alive when they reached the American coast. In 1850 about 11% of the population of the USA was of African origin.

Between 1850 and 1960 – the great period of voluntary European migration – 60 million people left the continent to settle in faraway lands. This figure represents about a fifth of the population of Europe at the beginning of this period.

Largely as a consequence of these developments, the Caucasian population of the world increased 5.4 times between the years 1750 and 1930, while in the same period the Asian population increased 2.3 times and the African population less than twice. By 1930 the proportion of Caucasians who did not live in Europe was one-third; and in 1970 it was more than half. At present more than one-fifth of Africans live outside Africa.

Migrations have always resulted in a redistribution and mixing of both genetic and cultural traits, including an exchange of technologies for resource use, and these have had a variety of different impacts on biodiversity.

Migration and trade calls for means of transport. Historically, transport was by ships on sea and trains of camels, horses, bullocks and humans on land. Transport over water is the least expensive, and ships have been the dominant means of transport for millennia. By 6000 BP it

was important in the Mediterranean and it has been speculated that the early city-builders of Mesopotamia, the Sumerians, had migrated to the region by sea between 5500 and 5000 BP.

For most of human history, boats and ships have been constructed of wood, and wood for shipbuilding was a major demand on forest resources, especially in medieval Europe (Thirgood 1981). Oak was the favoured raw material, and this demand caused extensive denudation of the oak forests of Europe. Extensive deforestation began around 1100 and continued until the fourteenth century, when it declined after the spread of the bubonic plague. Deforestation began again around 1500 and almost all the oak forest of Britain had disappeared by the sixteenth century. British interest in India's teak forests, to secure an alternative supply of timber for their merchant ships and navy, was a major motivation behind imperial ambitions. The teak plantations raised after the conquest of India were a significant cause of erosion of biodiversity over large forested tracts of peninsular India. So too was the demand for railway sleepers for the extensive network of railway lines built to facilitate transport of raw materials such as tea, jute, indigo and cotton out of India in exchange for manufactured goods from Britain, which were desired by Indian consumers (Rawat 1991).

Large-scale movements of material and people have also led to deliberate as well as accidental movements of living organisms. Such movements, for instance, led to the spread of tropical rat species as human commensals with the crusaders going back to Europe, and later to the outbreak of plague (Zinsser 1934). During their colonization of the world Europeans carried with them not only wheat, cattle and goats, but also many other European species which eliminated native biota over continental areas, such as American prairies, and on islands such as New Zealand (Crosby 1986). More recent times have witnessed the invasion of American weedy plants such as *Parthenium* and *Eupatorium*, all over the tropical world, leading to erosion of diversity of the native biota (di Castri *et al.* 1989; see 11.2.2.4 for a further discussion of the impact of introduced species).

Although the earliest settled communities most probably defended themselves against other human groups, the establishment of settled societies undoubtedly increased the reasons and potential for warfare by instituting clear ownership of resources and defined territories. The continually growing human demands for a variety of natural resources inevitably led to conflicts over access, and being a highly social species, humans have sometimes turned such conflicts into warfare. Other conflicts have arisen from attempts to keep aliens out of circumscribed group territory. Areas close to the boundaries of two contiguous group territories can be especially dangerous; these have often served as refugia for natural diversity in

tribal societies (Hickerson 1965). For example, *Arthashastra*, the Indian manual of statecraft composed some 2000 years ago, prescribed strict protection to wild elephant populations in forests at the boundaries of kingdoms (Kangle 1969).

Such conflicts can have a variety of effects on biodiversity. When a New Guinea highland tribe defeats another in a war, it does not immediately take over the territory of the vanquished. Instead, the winners cut down the fruit trees raised by them, perhaps to reduce the chances of the defeated people attempting to reclaim their territory (Rappaport 1984). As conflicts have intensified with the march of civilization, they have called for large investments in both defence and offence, putting greater demands on the natural world. Apart from these indirect demands, conflicts have directly inflicted much damage, for instance in the pursuit of the scorched-earth policy by warring armies. Defoliation in Vietnam, damage to marine life in the Kuwait war, and destruction of agricultural land in the Horn of Africa are recent examples of the impact of international conflicts on nature. Internal insurgencies also affect biodiversity, in part positively by reducing the pressures of commercial exploitation, in part negatively by allowing unregulated hunting.

This phase of human existence provides the first examples of intensive human alteration of and major destructive impact on the environment. It also provides the first examples of how environmental degradation became a main contributing factor to the collapse of vast societies.

11.1.5 The modern high-energy phase

The steadily expanding global trade in biological resources under increasingly centralized control of nation states and business corporations has been accompanied by an industrial revolution brought about by a series of technological advances. These advances have deployed large amounts of energy towards production, processing, transport and distribution of increasing quantities of goods. Until a few centuries ago, humans for the most part depended on their own muscle power, and that of their domesticated livestock, for production. Thus horses and oxen ploughed the land and pulled the carts, and artisans depended on their own muscle power to weave the cloth, forge swords and ploughshares and build houses and bridges. Wood fuel fired kitchen hearths and metal foundries, and wind power moved ships over oceans, but these energy sources could only be used at very moderate levels of efficiency.

Enormous supplemental sources of energy came about with the development of the steam engine, the internal combustion engine, electricity turbine, nuclear fission and solar cells. An associated development is the ability to synthesize a variety of chemical molecules serving a wide range of functions (i.e. building materials, fertilizers,

pesticides, synthetic drugs and plastics). All of this is contributing to even more profound changes in global biodiversity.

This modern high-energy phase is the dominant ecological and economical phase in the modern world today. It is characterized by very high and increasing rates of use of material resources and of energy (mainly in the form of fossil fuels) which is used for driving various kinds of machines. The basic ecological characteristics of farming remained unchanged until the nineteenth and twentieth centuries, but the industrial transition unleashed a new era in farming, with fundamental changes in agricultural practice. First, the use of machines powered by fossil fuels began to perform work previously done by humans or draft animals (e.g. ploughing, sowing and harvesting). Second, application of artificial fertilizers (mainly nitrogenous, phosphate and potash fertilizers) has progressively increased. And third, the genetic variability of cultivated plants has gradually declined.

Historically, as agriculture intensifies there is a tendency to emphasize a smaller number of crops (Boserup 1965). Thus in Asia the less intensive systems of cultivation involve several species and landraces of millets, amaranths and beans along with hill rice. With the introduction of wet paddies this gives way to stands of a few high-yielding varieties of rice and blackgram (*Phaseolus mungo*). This is because the technologies of more intensive crop production based on creation of relatively homogeneous environments tend to diffuse over wide areas.

Modern systems of agricultural production create extensive stands of single crops of low genetic diversity in the fields, while maintaining large amounts of genetic diversity so essential for continued success of plant breeding in *ex situ* storage. The modern farm production systems focusing on maximizing profits do so by wiping out environmental heterogeneity and by bringing in irrigation water and more recently chemical fertilizers, herbicides and pesticides. In these highly modified environments production tends to concentrate on genetically homogeneous stocks of a small number of species that may be grown most profitably in any given locality. These processes have led to a gradual loss of variety and genetic heterogeneity of cultivated plants being grown in any given locality, a process that is continually gathering pace.

The widespread use of synthetic pesticides to control parasites and diseases, and the cultivation of new high-yielding varieties of certain crops, are other changes that have resulted in considerable increases in yield per unit area, at the cost of losses in biodiversity.

The great increase in yield per hour of human labour is perhaps a more striking change. In the hunter-gatherer and farming phases, typically enough food was harvested to support each family. In the high-energy phase the situation

is very different. For example, in the 1970s, one farm worker would produce sufficient food for 50 people, and currently in Australia, one farmer produces enough for 85 people (two-thirds of whom live outside Australia).

Intensification of agriculture and livestock production has permitted the gradual differentiation of human populations into those directly dependent on biological resources produced with their own labour, and those dependent on the surplus production of the countryside. In the modern high-energy phase of society, the great majority of human beings do not participate in direct subsistence activity and so are far removed from the realities and consequences of food acquisition and production.

Dasmann (1988) distinguishes these two categories of people as 'ecosystem people' and 'biosphere people'. Ecosystem people are the farmers, herders, fishers and hunters who depend largely on natural resources gathered or produced from their own immediate surroundings: they experience at first hand the consequences of their patterns of resource use. Biosphere people are dependent on much larger systems, and typically are well insulated from the environmental consequences of their use of resources. If their consumption leads to over-exploitation, they can easily move on to other systems through the market-place. Early 'biosphere people' included the warriors, priests, bureaucrats, merchants, and artisans of the agrarian societies, while later biosphere people include those engaged in organized services and industries in modern societies who have access to the resources of the entire biosphere through global markets.

As agriculture and livestock production have become a part of modern industrial enterprise, farmers too are moving into the category of biosphere people. But over much of the historical period farmers have been ecosystem people, and to a large extent they remain so in parts of the developing world. The division into ecosystem and biosphere people is a great simplification, and different groups can be located at different places along a continuum of dependence on locally available resources. However, Dasmann's classification is a useful conceptual tool for understanding different relationships between people and biodiversity.

Subsistence farmers largely producing for domestic consumption or local level exchange – behaving as ecosystem people – have been motivated to cultivate a variety of plant species to fulfil their own manifold demands for food, fibre, fuel and medicine. They have also attempted to minimize the risks of large losses of plant production due to unfavourable weather events or outbreaks of pests. They would therefore tend to nurture a diversity of species, as well as a variety of landraces of many of these species. As farmers became linked to outside markets, they no longer had to produce locally a whole range of food, fibre and medicinal plants; indeed markets

could bring to them a much greater diversity of plant products from many different regions than could be produced locally. But farmers also required cash to buy these products from the markets, and hence their interest gradually shifted to managing on-farm production to maximize its market value, rather than generating a variety of products for local consumption, or to ensure buffering against risks.

The new methods are extraordinarily dependent on continual external inputs – especially energy-costly artificial fertilizers and pesticides, and considerable input of energy.

The development of the steam engine ushered in a new kind of technology of overwhelming ecological significance, powered by the combustion of fossil fuels. Another set of scientific advances relating to the use of energy that has had an enormous influence on human affairs involved the discovery of electricity and electromagnetic phenomena.

Fossil fuel driven generators are the largest source of electricity, with a usual energy efficiency of about 30%. Hydroelectric plants contribute to around 6% of the world's overall electricity budget. Over 350 000 PJ of extrasomatic energy per year is currently being used by humankind, which is a 10 000-fold increase in the past 400 generations. For example, the average North American uses 100 times more extrasomatic energy than the average hunter-gatherer.

Ecologically important distinctions exist between the direct or indirect forms of non-fossil fuel derived energy (solar power, hydroelectric power and wind power) and fossil fuels and nuclear power. No incidental chemical by-products are released into the environment in the case of the former. Fossil fuels result in the liberation of carbon dioxide, carbon monoxide, hydrocarbons, and sulphur and nitrogen oxides; and nuclear power produces highly radioactive substances. Furthermore, the use of solar power does not release additional heat to the environment beyond that which would in any case be given off as a consequence of the solar radiation of the Earth.

Recent decades have also seen the growth of the production of synthetic materials used for a wide range of purposes, including the manufacture of clothing, utensils and countless other commodities. This industry dates back to the middle of the last century, when a hard flexible transparent substance known as celluloid was made by mixing nitrocellulose and camphor. The environmental impacts of plastics are under considerable criticism. On the one hand, it is argued that they are 'biosphere friendly', because it takes less energy to produce a plastic product than a comparable one made from glass or aluminium. On the negative side, the lack of degradability of plastics represents hazards for sea birds, marine mammals and other creatures. In some cases the processing and manufacture of plastics also results in the release of toxic chemicals.

For humankind the possibility of resource scarcity is far less dangerous than that of 'choking in its own wastes', or severely damaging the productive processes of the biosphere. Broadly speaking, two kinds of waste are produced by high-energy societies. First are what can be called the biometabolism products of society which are the organic waste products (i.e. sewage, unused food and organic fibre). Usually little of this type of waste is returned to the soil so natural nutrient cycles are disrupted. The second type of waste consists of those waste products resulting from the technometabolic aspects of society, including industrial activities, such as plastic production, the use of machines, and the by-products of extrasomatic energy use. As discussed previously in this volume, human activities are also resulting in the discharge into the atmosphere of gases that contribute to global warming. The chlorofluorocarbons (CFCs), the synthetic products of our industrial society which are responsible for the thinning of the ozone layer are, volume for volume, many thousands of times more potent as greenhouse gases than carbon dioxide.

Needless to say, the control and use of material resources, and the material benefits derived from them, are far from evenly distributed within the populations of most high-energy societies. The disparities that exist in the intensities of resource use between populations in the developed and developing regions of the world are even more striking. The industrially developed world, which contains about one-fifth of the total human population, uses 90% of the non-renewable resources produced, meaning that on a per capita basis the populations in these countries are using about twenty times more non-renewable resources than populations in the developing countries. For example, the United States, which has 5% of the world's population, uses 27% of the materials extracted. Per capita, this is 36 times more than in the developing world. It is not easy to provide an accurate picture of the changing rates of use of different mineral resources either by humankind as a whole or by separate societies. However, it stands to reason that increasing industrial productivity involves increasing use of resources. The impact of this on biodiversity is unclear, but it seems inevitable that expanding human consumption of resources that means fewer resources will be available for other species.

In addition, in this phase, urbanization processes have increased, with a higher degree of artificialization. Simple shelters that once involved wooden poles and hides, or just shallow caves, have developed into enormous human-made caves of brick and mortar, concrete and steel. Simple beaten footpaths have been converted into kilometre after kilometre of paved and tarred roads. Such habitats especially favour a few commensals of humans; rock doves and swifts fond of rocky crags are at home in a forest of human-made crags as are black rats and house mice in human-made burrows. Cities have their own biodiversity-

rich areas in gardens and parks where high levels of diversity may be created by artificially collecting species from around the Earth, often in environments specially created to suit them (Section 13.3.8.1).

Apart from directly moulding large areas, urban concentrations, highways and railroads affect natural diversity through making ever-growing demands on resources of far-flung areas. Pink granite is mined in south India, destroying extensive dry deciduous forests on its hill tracts, to make tiles for the bathrooms of the urban middle class and facings for buildings in western Europe. The fuelwood demand for baking bricks to support the unceasing expansion of Calcutta is leading to the slow demise of the world's largest mangrove forest in Sundarbans.

Urban metropolises may appear to be burgeoning, crowded, overstressed habitats with little room for nature. But hidden within the concrete maze, a surprising amount of wildlife still survives (Section 13.3.8.1). A small lake in the centre of Hanoi in Vietnam harbours the only surviving population of the giant freshwater turtle (*Pelochelys bibronii*) (Quy 1995). Another outstanding example of such survival is the Delhi Ridge Forest which runs through the capital city, and is covered by dense dry deciduous forest and thorn scrub. This 7770 hectare sliver of vegetation harbours a large amount of biodiversity, including nearly 200 species of birds.

11.1.6 History of conservation traditions

The consequences of advances in human technology through the ages, for the life experience of humans and for the relationships between human society and the biosphere, have been multiple and wide-ranging.

The preceding discussion supports the conclusion that the Earth has witnessed an ever-accelerating erosion of biological diversity over the past 10 000 years as numbers of people and their abilities to affect the natural world have grown steadily. But people can and do modify their behaviour on the basis of their perceptions of the long-range consequences of their actions. At many different times and in many different cultures, people have apparently been motivated to conserve, even enhance, biological diversity and have evolved a variety of cultural practices that seem to contribute to this end. But establishing a connection between specific practices and conservation or enhancement of biological diversity is by no means a simple matter; for the overtly declared purpose of a practice which seems to help conserve biological diversity may in fact be quite different. Thus, in South Asia many sacred ponds have helped conserve the indigenous fish fauna. But people leave these ponds alone out of respect for some deities, not with an expressly declared purpose of conserving fish diversity. It is then quite possible that many practices that seem to promote conservation may have originated from different

motivations, while others declared as promoting conservation may in reality achieve something very different. Accepting that this may be so, it is still of considerable interest to review the variety of cultural practices that (a) apparently serve to conserve or enhance biological diversity – whether or not that is their declared purpose, and (b) expressly purport to conserve or enhance biological diversity – whether or not that is the actual result or the genuine underlying motivation.

Historically, people colonizing new environments or undergoing rapid economic development have not been concerned, at least in the initial phases, with conservation of biodiversity. But once an area is settled or developed, humans begin to accumulate experience of the impact of their resource management practices. They are able to see the resource depletions that follow non-sustainable harvesting pressures, and the recoveries that sometimes follow when, for some reason, harvesting pressures are reduced. Furthermore, when living in a given locality generation after generation, they might perceive self-interest in moderating harvesting efforts so that harvests are improved in the long term. This would be particularly so if they depend largely on harvests from a circumscribed area, and are using technologies that are not continually leading to higher and higher levels of harvesting efficiencies. Many small-scale, autonomous hunter–gatherer or agrarian societies have settled in regions where they control well-defined territories from which most resources garnered were likely to fulfil these conditions. Such people may then have had the knowledge base, the motivation, and the capability of moderating resource harvests so as to serve long-term, group interests in sustainable use and conservation of natural diversity (Gadgil and Berkes 1991).

A variety of such practices of moderating harvesting efforts are known historically from various parts of the world. Refugia immune from harvests may take the form of sacred groves, or ponds, or pools along river courses, or lagoons of coral islands where entire living communities are protected from human interference. Sacred groves may conserve species that have disappeared elsewhere; for example, the Botanical Survey of India discovered a new species of leguminous climber, *Kunstleria keralensis*, in a sacred grove on the densely populated coast of the state of Kerala. In Pakistan representatives of original tree species still persist in old Moslem graveyards, because of a taboo against cutting these trees. Khan (1994) used these tree stands to reconstruct the past distribution of the thorn forest in Punjab. In China, royal gardens, royal cemeteries, ancestor temples and Buddhist temples have long maintained examples of natural vegetation in excellent condition, although many of these are now disturbed. And the only surviving population of a freshwater turtle, *Trionyx nigricans*, survives in a sacred pond dedicated to a Moslem saint in Bangladesh (Gadgil *et al.* 1993).

The restraints on harvesting may involve giving protection to keystone species that may support the persistence of a range of other species. Thus, fig trees belonging to the genus *Ficus* are recognized as important sources of fleshy fruits available in seasons when no other tropical forest species are producing fleshy fruits. *Ficus* trees thereby promote persistence of a number of insect, bird, bat, squirrel and primate species for which they serve as a critical resource in a period of fruit shortage. All species of *Ficus* are even today to an extent protected as sacred trees through much of tropical Asia and Africa, where the local communities are aware of this ecological role.

Harvesting restraints also include the protection of critical stages in the life histories of species that are especially vulnerable to overharvesting. Thus a nomadic hunting tribe of Western India has the tradition of releasing any pregnant does or fawns of antelope or deer caught in their snares; and egrets, storks, herons, pelicans, ibises and cormorants at their colonial nesting colonies are given immunity from hunting over most of India, although these birds are hunted in the non-breeding season. Finally, in many Asian villages fruit bats are not hunted at their daytime roosts, but may be killed at a distance from the roost during the night (Gadgil *et al.* 1993).

A rich literature of such traditional conservation practices indicates that they have been a common feature of many cultures over many years (see, for example, Suzuki and Knudtson 1992; Maybury-Lewis 1992; Western and Wright 1994). This literature indicates that such practices serve the group interests of communities and that they remain viable only so long as (a) local communities continue substantial levels of dependence on resources garnered from their immediate vicinity, (b) they have full control over the local resource base, and (c) they retain a sufficiently high level of internal cohesion. These conditions are no longer fulfilled when outside state or corporate bodies establish control over natural resources, when access to markets begins to bring in resources from outside and local resources become a source of cash income, and when local communities lose their traditional social organization (Ostrom 1990). In many parts of the world, therefore, hunter–gatherer–shifting cultivator communities are today involved in excessive harvests and depletion of natural biodiversity (Redford 1990, 1992).

Historically, the more advanced agrarian societies seem to abandon most of the conservation practices of technologically less advanced communities. Such societies do, however, provide an example of a new type of conservation practice. With domestication of livestock, meat became available in abundance without having to resort to hunting. However, hunting remained a pleasurable pastime, and provided training for warfare. So the elite established hunting preserves in which resource harvests were severely restricted; and hunting the larger birds and

mammals, pheasants and deer, wild pigs and bear was the exclusive privilege of nobles. In mediaeval India, Hindu kings and Moghul nobles maintained extensive hunting preserves that have since become the nuclei of many of the nature reserves of modern India (Gadgil and Guha 1992). Europe, too, had a system of hunting preserves, for example, the Sherwood forest in Britain and Coto de Doñana in Spain. The elite also maintained menageries with falcons and cheetahs used in the hunt, and a whole range of other animals kept as a curiosity. The best known instance of conservation by these aristocratic zoos is the survival of the Chinese Père David's deer in the Duke of Bedford's zoo in Britain (Grzimek 1990). Successful breeding programmes in zoos have also made possible the reintroduction into the wild of two mammals: Przewalski's horse in Mongolia and the Arabian oryx in Oman.

Following European expansion beginning in 1500s the whole world became interconnected by networks of trade, stimulating interest in the biodiversity of the Earth. This interest was novel in creating people who were curious about a very large biota from diverse ecosystems, in contrast to the traditional in-depth knowledge of a much more limited biota of a circumscribed area in which the ecosystem people operated. There had of course been other attempts at such systematization of knowledge in agrarian societies, notably in developing the pharmacopoeias for the Chinese and Indian systems of herbal medicines. But they had dealt with a more limited range of diversity. Coping with the global range of diversity called for a systematization of knowledge of biodiversity on an unprecedented scale, demands that stimulated such innovations as the Linnaean system of classification of living organisms, von Humboldt's classification of world vegetation, and Wallace's delineation of biogeographic provinces. These achievements were accompanied by van Leeuwenhoek's discovery of the microbial world (Grove 1992).

As the world trading system emerged, many earlier conservation practices were initially completely rejected. But then newer ones emerged, including practices such as the setting up of National Parks or laws to protect endangered species. These attempts have taken on conservation as a responsibility of the state apparatus, often to be practised in isolation from the economic forces in the wider society and through exclusion of extractive human uses (Koppes 1988). These attempts are moderately successful in the industrial countries, but state-directed conservation is more difficult in the developing countries where natural resources must simultaneously provide raw material for the larger economy within the countries and abroad, and meet the subsistence demands of a growing rural population (McNeely *et al.* 1994).

11.1.7 Historical trends in property rights

Over historical periods, flows of biological and other resources from one region to another have progressively

assumed a more and more global character. Managing these flows has involved increasing levels of tighter, centralized control by nation states and their bureaucracies, and by business corporations. Control over environmental resources at the hunter-gatherer as well as shifting cultivator stage is basically in the hands of small kin groups, several of which make up some specific tribal group inhabiting and controlling a larger contiguous tract. As cultivation intensifies, village communities tend collectively to control resources in a similar fashion, though land under cultivation may now assume the character of private property. However, the non-cultivated lands, pastures and woodlots tend to be managed and controlled as community property. Herders, including nomadic herders, may also control pastures as properties of clans.

As populations have grown and societies have become more urbanized, however, such community-managed lands and waters have tended to change hands. An early well-known example of these was the enclosure of commons by English manorial lords in the mediaeval period. The theory was then developed that private or corporate ownership of property was appropriate because the state could expropriate surpluses by taxing such property, and redistribute benefits to the populace (and especially to support the cities). The residual property was to be claimed by the state itself. This scheme left no room for control over common property resources by communities, which were themselves beginning to disintegrate in response to the emerging market economy. This approach was extended to the colonies of European nations, since in these colonies large tracts of forest and pasture lands were under control of local communities for extensive rather than intensive use; such areas were often perceived by Europeans as 'wilderness' or 'wastelands' (Boyden 1992). Most of these lands were taken over as state property without any compensation being made to local communities. This in effect converted huge areas into open access property, since the state was in no position to exclude totally the use of some resources by local communities (Hardin 1968). In such tracts, local communities retained some privileges of use, but no rights for controlling overuse by any members of their own communities, or by outsiders. Huge tracts of earlier community-controlled, biodiversity-rich lands were thus converted to no-man's-lands subject to universal abuse and erosion of biodiversity (Gadgil and Guha 1992).

While this was the general pattern, community management and protection of biodiversity did persist in isolated pockets in several parts of the world. Thus residents of Kallabbe in Western Ghats of Karnataka managed to retain control over their village forest after its take-over by the state between the 1860s and the 1920s. In the 1920s a system of village-controlled forests was revived in this district in response to the forest destruction that followed the dismantling of community control. So

village community-based forest management was officially reinstated in a small number of villages, including Kallabbe. A survey in the 1980s revealed that the Kallabbe village forest was among the most biodiversity-rich tracts in the district (Chandran and Gadgil 1993).

However, not all colonies were the same. A few recognized the negative impacts of settlement and sought to correct them. On Mauritius, the French colonial government passed an ordinance in 1769 which stipulated that 25% of all land-holdings were to be kept as forest, particularly on steep mountain slopes, to prevent soil erosion; all denuded areas were to be reforested; and all forests within 200 metres of water were to be protected. In 1803, clearing of forest was forbidden higher than one-third of the way up a mountain side (Grove 1992).

In some parts of Europe, the community control of common property remained strong through the period of rampant deforestation of Europe. By the mid-nineteenth century Switzerland retained only about 4% of its land under forest cover, leading to serious problems of landslides and siltation. The communities then rolled back the tide of forest loss, and successfully built back the forest cover to the present 25% (WRI 1994). As of today these secondary forests remain under the control of powerful local community-based governments. But such examples of effective community control, whether of ecosystem people as in Kallabbe or of biosphere people as in Switzerland, are exceptions. Over much of the world, biodiversity-rich common lands and waters are largely under control of the state, and have often been permitted to lose much of their biodiversity.

11.2 The impact of human activity on biodiversity

11.2.1 Introduction

The current impacts of humans on biodiversity are both direct and indirect. The direct mechanisms include habitat loss and fragmentation, invasion by introduced species, the over-exploitation of living resources, pollution, domestication and selection, global climate change, local and industrial agriculture and forestry. But these are not the root of the problem. Biotic impoverishment is an almost inevitable consequence of the ways in which the human species has used and misused the environment in the course of its rise to dominance: the factors that have led to the expanding ecological niche of humans are indirect causes of the loss of biodiversity. Sections 3 and 8 have assessed the current status of biodiversity and showed that humans have been a major force in determining this status. Section 6 has assessed human impacts on ecosystem functioning in various biomes. Chapter 11.1 has assessed knowledge about the history of human impact on biodiversity. This chapter will assess the mechanisms of human impacts – both positive and negative, direct and indirect – on biodiversity.

The ‘Global Biodiversity Strategy’ (WRI, IUCN, UNEP 1992) identified both direct and indirect mechanisms that affect current levels of biodiversity, nearly all of which have significant human components. The direct mechanisms, following Soulé and Wilcox (1980), Diamond (1985) and Pimm and Gilpin (1989), include:

- exploitation of wild living resources;
- expansion of agriculture, forestry and aquaculture;

Key messages

- Humans have endeavoured, rather successfully, to acquire their growing biomass needs from intensifying the productivity of a small number of domesticated species. Populations of the favoured species have then reached high densities in limited areas manipulated as farmlands, pastures, fish ponds or plantations.
- Humans have been engaged over historical times in steadily improving technology and expanding the range of biological resources useful to people. This has inevitably been accompanied by a retreat of the natural world; and an erosion of biodiversity.
- As natural forests and fish stocks have declined, the historical trend is to devote greater effort to plantations and aquaculture. These replace large tracts of natural diverse ecosystems with species-poor systems supported by high levels of technological inputs; they also promote extensive use of pesticides and other poisonous substances resulting in more widespread negative impacts on biodiversity.
- As human technological capacities have increased, so have inequities within and between societies. The powerful social segments within nations have access to natural resources from wide catchments, suffering few of the negative consequences of environmental degradation and erosion of biodiversity. Rather, they have a strong vested interest in continued growth of the artificial at the cost of the natural, often in another country. This disrupted link between maintenance of biodiversity and the quality of life of those who ultimately decide the course of economic activity is at the base of the growing pace of erosion of global biodiversity (Shiva *et al.* 1991).

- habitat loss and fragmentation;
- indirect negative effects of species introduced by humans;
- indirect positive effects of species introduced by humans;
- pollution of soil, water and atmosphere; and
- global climate change.

The indirect mechanisms identified in the ‘Global Biodiversity Strategy’ and elsewhere are arguably more significant and indicate the foundations of the human impact on biodiversity. They include:

- human social organization;
- the growth of the human population;
- natural resource consumption patterns;
- global trade;
- economic systems and policies that fail to value the environment and its resources;
- inequity in the ownership, management and flow of benefits from both the use and conservation of biological resources.

However, the picture is seldom simple, and in many cases the human impacts on ecosystems can have positive, negative or neutral effects on various elements of biodiversity. Happold (1995), for example, showed that

different groups of mammals had different general responses to human interference (drawing on information from Africa) (Table 11.2-1).

The following paragraphs attempt to assess the current evidence on the impacts of human activities on biodiversity, using the categories listed above while recognizing that these impacts invariably involve a complex interplay of biological, social, historical, economic and political factors. The complexity of human impacts on biodiversity is indicated by Grainger (1992), who presented an example from deforestation (Box 11.2-1), Lamprey (1975), who showed the linkages among the various factors affecting desertification in northern Kenya (Figure 11.2-1), and Tucker and Heath (1994), who attempted to unravel the many threats to the 54% of European birds which are experiencing substantial population declines (Figure 11.2-2).

In any case, it is clear from several studies (e.g. Moyle and Leidy 1992; Frissell 1993; Angermeier 1995) that many extirpations of species are not explainable from knowledge of ecological attributes or particular anthropogenic impacts but are probably due to the cumulative effects of multiple impacts. Clearly, additional research is required to improve our understanding of such multiple and possibly synergistic or non-linear influences. Further study is required on the relationships between the biota and other ecological components, including sub-surface and surface water, riparian zones, watersheds, landscapes, and human influences on all of these (Karr 1991; Angermeier and Williams 1994; Angermeier and Karr 1994).

Table 11.2-1: Responses of mammals to human interference (modified after Happold 1995).

Group (examples)	Responses	Species characteristics	Reasons for response
A. Populations decrease (elephants, rhinos, large/medium artiodactyls and carnivores, most primates)	Negative	Large size Low reproductive rate Compete directly with humans/stock for resources	High value to humans High trophy value Cause damage High monetary value Competition for land Hosts for diseases
B. Populations remain static (many medium-sized mammals, many orders)	Neutral	Variable size Moderate reproductive rate Limited competition with humans/stock for resources	Less value to humans Limited value for trophies Low monetary value Limited competition for land Not known as hosts for diseases
C. Populations increase (certain small rodents, shrews, bats, other small species)	Positive	Usually small size Usually higher productive rate Limited competition with humans for resources, or good at exploiting human resources	No value or limited value to humans Difficult to hunt

Box 11.2-1: The causes of deforestation (Grainger 1992).

A. Immediate causes – land use

- 1. Shifting agriculture
 - (a) Traditional long-rotation shifting cultivation
 - (b) Short-rotation shifting cultivation
 - (c) Encroaching cultivation
 - (d) Pastoralism
- 2. Permanent agriculture
 - (a) Permanent staple crop cultivation
 - (b) Fish farming
 - (c) Government sponsored resettlement schemes
 - (d) Cattle ranching
 - (e) Tree crop and other cash crop plantations
- 3. Mining
- 4. Hydro-electric schemes
- 5. Cultivation of illegal narcotics

B. Underlying causes

- 1. Socio-economic mechanisms
 - (a) Population growth
 - (b) Economic development
- 2. Physical factors
 - (a) Distribution of forests
 - (b) Proximity of rivers
 - (c) Proximity of roads
 - (d) Distance from urban centres
 - (e) Topography
 - (f) Soil fertility
- 3. Government policies
 - (a) Agriculture policies
 - (b) Forestry policies
 - (c) Other policies

Figure 11.2-1: Some causal factors in desert encroachment in northern Kenya (after Lamprey 1975).

Figure 11.2-2: Threats which have contributed to the decline of the 278 bird species, which have substantially declining European populations (total bird species regularly occurring in Europe = 514). (Modified from Tucker and Heath 1994.)

11.2.2 The mechanisms of human impacts on biodiversity
Human impacts on biodiversity become global in two main ways. First, by affecting a globally dynamic system, such as the atmosphere, world climate or sea level; and second, by occurring in a localized or patchwork fashion in enough places to lead to a globally significant impact (Turner et al. 1990) (Box 11.2-2). The following paragraphs discuss the mechanisms of human impacts.

11.2.2.1 Exploitation of wild living resources

Wild resources are harvested by rural people throughout the world for food, shelter, traditional medicines, dyes, oils, intoxicants, fuel, beverages, fibres, tools, religious purposes and cash income. Such harvests are motivated by cultural traditions, survival needs and, to a greater extent today, for

cash income to supplement earnings from other sources. For example, in Niger, 99% of the domestic energy (and 80% of primary energy) requirements are met from wild-harvested wood. Tiega (1993) and Anstey (1991) estimated that 75% of the meat production in Liberia was derived from wild harvests; and Murdock (1958) determined that 83% of 714 ethnic groups in Africa and Madagascar were dependent on wild resources, and 50% relied on fishing, hunting and gathering of wild plant products.

Historically, the environment was carefully manipulated to maintain optimum levels of species for human consumption. To achieve the desired effect, active management was needed. Native Americans in the Pacific Northwest of the United States, for example, conducted burns in the forests near their encampments so as to

Box 11.2-2: Types of global environmental change affecting biodiversity (modified after Turner *et al.* 1990).

Type	Characteristic	Examples
Systemic	Direct impact on globally functioning system	(a) Industrial and land-use emissions of ‘greenhouse’ gases (b) Industrial and consumer emissions of ozone-depleting gases (c) Land cover changes in albedo
Cumulative	Impact through world-wide distribution of change	(a) Groundwater pollution and depletion (b) Species depletion/genetic alteration
	Impact through magnitude of change (share of global resource)	(a) Deforestation (b) Desertification (c) Industrial pollutants (d) Reduction of population of certain species

facilitate hunting and ensure a plentiful supply of deer (Fisher 1992). Posey (1982) has argued that certain game species would not occur in forest unmodified by humans, and important game species of mammals such as deer, tapir, and collared peccary reach much higher densities in modified areas. Not all traditional hunting-gathering was within the capacity of species/ecosystems, and with increasing demands in recent times, such activities have become threats to many species. In India, some orchids used for medicinal purposes, for example *Paphiopedilum druryi*, *Dendrobium pauciflorum*, *D. nobile* and *Diplomeris hirsuta*, are threatened (Ayensu 1983). Several species of hornbills are also threatened in northeast India due to hunting, traditionally carried out for the supposed medicinal value of their casques, flesh, fat and bones.

The extraction of elements such as fuelwood by rural communities, perhaps once within the carrying capacity of surrounding forests, has now crossed this limit in many areas. Lean *et al.* (1990) identify the fuelwood shortage as ‘the poor man’s energy crisis’ which is affecting 2 billion people world-wide. They calculate that currently 100 million people in developing countries cannot get sufficient fuel to meet energy needs and almost 1.3 billion are consuming fuelwood faster than it is being replenished. A direct result of this shortage is that people are forced to use animal dung as an alternative source. For example, ESCAP (1990) reports that 70% of the cooking needs in some parts of rural India are met by use of animal dung, representing a serious loss of nutrients which would normally be used to replenish the soil. In addition, in India, total fuelwood demand is 235 million m3, but only 40 million m3 can be harvested sustainably from its forests (FSI 1987); a

substantial part of this demand is from urban sources. Leach (1987) argues that rural fuel demand is not a major cause of deforestation; but Davidson (1992) and Ranganathan *et al.* (1993) point out that urban and industrial demand for fuelwood and charcoal may be major factors in forest degradation and deforestation.

Numerous forest, fisheries and wildlife resources have been over-exploited, sometimes to the point of extinction (IUCN 1994). Many historical extinctions have resulted from the human harvest of food, but the search for precious commodities – notably ivory and rhinoceros horn – and for pets, curiosities, and collectors’ items has also impinged on some populations and obliterated others (Myers 1979; Ehrlich and Ehrlich 1981; Nitecki 1984; Wilson and Peter 1988).

Any use of biological resources results, to some degree, in alteration of ecosystems, and often in their simplification, an effect which may result in ecosystem instability. The harvest of biomass from ecosystems constitutes a mortality factor for the species harvested, which may add to natural mortality, or be compensatory, i.e. replacing parts of natural mortality. Most human harvest, however, imposes selection that differs from the natural one, affecting the gender, age or size groups present.

The impact of harvesting of material components of biodiversity varies with the type of harvesting and the harvest rate, with a gradient from low impacts on populations and ecosystems (e.g. sport fishing) to high-level harvest of manipulated and homogenized systems (e.g. farming). For instance, up to a certain degree, collection of dead wood for firewood or the picking of berries may be of little consequence for biodiversity. At

high harvest rates, however, removal of dead wood implies a reduction of food and substratum for large groups of species (e.g. Siitonen 1994). Moreover, picking of berries at extreme harvest rates may imply a change in selection pressure or reduction of recruitment rates for the species in question, as well as removing energy which would otherwise either be available to native fruit-eating birds, mammals and insects or form part of the nutrient cycle in the forest.

Hunting has exterminated many endemic species, particularly on islands (Olson 1989; Diamond 1989). However, hunting may also lead to the demise of species in less confined habitats (Caughley 1994), and circumstantial evidence indicates that prehistoric humans were instrumental in the disappearance of many large mammals in the Americas, the Mediterranean, Madagascar and Australia (Janzen and Martin 1982; Martin and Klein 1984; Owen-Smith 1987; Burney 1993). Although modern hunting based on scientifically developed management plans may actually increase population numbers, it is usually selective, implying increased mortality within sex or age groups, altered population structures, life histories and genetic structures and often the removal of some of the most fit males (Skogland 1990).

Harvesting of timber from a natural forest has profound effects on the biodiversity of the forest ecosystem (e.g. in tropical forests: Sayer and Whitmore 1991; Whitmore and Sayer 1992). Harvesting of timber reduces diversity in terms of tree species and structural variation (Järvinen *et al.* 1977; Kouki 1994), although young, early successional stands which develop soon after harvesting may have high biodiversity (Kimmins 1992). Forest trees compete with other plants, provide food for various animals, and dominate the physical structure and microclimatic conditions of the ecosystem, creating habitat and substratum for other species. In unharvested forests, old, dead and decaying trees are food and substratum to many late succession organisms (Whitmore 1984; Maser, 1988; Väisänen *et al.* 1993). Harvesting for timber and fuelwood removes these old and dead trees, and may lead to the disappearance of a number of the specialist species (Raphael and White 1984; Angelstam and Mikusinski 1994; Siitonen 1994).

In addition to these effects, removal of biomass may also influence the nutrient cycling in ecosystems. Clear-cutting removes biomass from the ecosystem and changes its physical structure to an extent that alters microclimate, nutrient cycles and nutrient availability (Bormann *et al.*, 1977; Saulei 1984; Malingreau and Tucker 1988), influencing regeneration processes and thereby species diversity in all subsequent successional stages. This aspect may be more pronounced in moist tropical forests than in temperate forests (Maser 1988), as tropical forests have a larger proportion of their biomass stored in the living vegetation (Whitmore 1984).

Harvest of biomass from natural ecosystems may also be indirect, through the grazing of domestic animals. It is well known that heavy grazing may seriously alter ecosystems in subarctic, temperate and tropical regions (e.g. Bond 1993). The effects of grazing depend on the species of grazing animals, for example domestic goats may destroy the plant roots, promoting soil erosion, whereas cattle only eat the above-ground parts of the plants (although, being heavy animals, they can cause soil erosion indirectly through soil compaction resulting in higher runoff).

While grazing may directly alter plant species composition and productivity, it may also indirectly affect invertebrate species which often play an important role in the maintenance of stability in ecosystems. Mott and Tothill (1994), reviewing the losses in diversity in Australian savannahs, document the large changes in abundance and diversity in ants, soil detritivores and termites as a result of grazing practices. Even at low stocking rates substantial changes in the fauna have been recorded: free-ranging, low-density livestock have been associated with a 60% reduction in small rodents and marsupials in the Central Australian region since pre-European times (Morton and Baynes 1985). A study in China showed that changes in plant communities through grazing by domestic animals directly affected the species composition of grasshoppers, with moderate grazing preserving more diverse grasshopper populations with a lower proportion of pest species (Le 1994). On the other hand, Dodd (1994) discusses the need for caution in explaining the vegetational changes in Africa's arid lands in terms of overgrazing of domestic livestock. While the high densities of animals near high-volume watering points and villages and on rangelands closely linked to crop agriculture in Africa can permanently and severely alter vegetation, he found no scientific evidence that either nomadic or commercial use of livestock has caused irreversible changes in range vegetation away from these areas.

Among wild ungulates, harvesting can affect population growth by influencing reproductive traits such as age at maturity, twinning rate, and proportion of reproducing females (Jonsson *et al.* 1993). These reproductive traits vary with body size and age of the animal, and show geographical variation reflecting differences in environmental conditions and adaptations. There is a negative correlation between age at sexual maturity among moose and life-time reproductive success; cows that mature earlier begin to produce twins sooner than cows that mature later and as a result have higher reproductive output.

Over-exploitation can severely disrupt ecological communities. While it is generally agreed that whaling represents one of the most dramatic alterations of mammalian species diversity by humans, the quantitative effect of whaling on deep-sea biodiversity is difficult to

evaluate because of the lack of information on historical distribution of most whale populations (Evans 1987; Butman *et al.* 1995). But of the large whales, two are endangered and five others are threatened (IUCN 1993), all due to hunting by humans. Populations of all the other large whales have been significantly reduced by human hunting.

Recent evidence (Smith *et al.* 1989; Bennett *et al.* 1994; Butman *et al.* 1995) indicates that these vast reductions in whale populations may have altered the biodiversity of the deep oceans by greatly diminishing an important source of organic matter for the chemosynthetic-based communities associated with hydrothermal vents: decaying whale skeletons apparently serve as stepping-stones that support a chemosynthetic-based deep-sea community of novel organisms. Butman *et al.* (1995) conclude that changes in the distribution and the severe reduction in the supply of whale carcasses may have directly affected deep-sea community composition in the world's oceans. The unique skeletons-associated community was discovered only in 1987 (Smith *et al.* 1989), but the community is apparently being threatened by the reduction in whale skeleton supply which means the spatial interruption or even obliteration of the stepping-stone between hydrothermal vent fields and other microbial-reducing communities. This problem requires more study, especially in view of the great interest that biotechnology has in the unique organisms of the deep sea.

Overharvesting of fish can also have profound systemic effects. For example, over-exploitation of the Atlanto-Scandinavian herring and capelin led to the collapse of many large fish, sea bird and sea mammal populations. Moreover, heavy exploitation of selected species in a multispecies ecosystem will influence the balance among competitors and their predators, prey and parasites, changing the dynamics of the system (Beverton 1990; Ajiad *et al.* 1992). Whether marine multispecies systems disrupted by heavy exploitation will return to their original or some alternative dynamic equilibrium after the harvesting is stopped is not known (Steele and Henderson 1984).

All the recorded extinctions of fish species and subspecies in the present century are from freshwater habitats. Fishing was involved in only a few, and only as a minor factor. The main causes were loss or degradation of habitat, interruption of migration routes and the introduction of exotics (Beverton 1993). This does not mean, however, that human harvesting is unimportant for the persistence and well-being of the exploited populations. On the contrary, fisheries frequently have depleted fish populations and thereby heavily influenced the diversity and dynamics of aquatic ecosystems (e.g. Pitcher and Hart 1982).

The ecosystem of the Barents Sea changed drastically due to the depletion of the herring stock from the mid-1950s to 1970 and the depletion of capelin in the mid-

1980s (Hamre 1994; Gjosæter *in press*). The Arctic cod population decreased due to lack of food (capelin and herring), with cannibalism and low individual growth rates as the result. The coastal cod fisheries were hit by the worst crisis on record. Furthermore, because of lack of capelin and young herring, seabirds, particularly the highly specialized fish-feeding guillemot, died by the thousands (Vader *et al.* 1990). Moreover, large numbers of starved harp seals invaded the Norwegian coast and many died as they were caught incidentally by the Norwegian coastal fisheries (Haug *et al.* 1991). The collapse of stocks and fisheries in the 1980s seems largely to be a result of the herring fishery in the 1960s but the crises in the whole ecosystem were not triggered until the climate changed in the early 1980s and the recruitment conditions of herring and cod were improved. The large capelin fisheries probably added to the shortage of prey in the mid-1980s. Since the late 1980s recruitment conditions for cod and herring have improved and these two stocks are now increasing due to favourable environmental conditions. This example illustrates that the depletion of prey populations has significant effects on the predators; but it also shows that at least some depleted fisheries often can rebound relatively quickly once harvesting pressure is reduced.

Apart from a shift of fishing effort towards the smaller end of the size spectrum of the fish community, clear-cut evidence of the effects of fishing on the substantive structure and function of marine ecosystems is scarce. The most extreme of the above collapses certainly caused detectable changes, for example the decline of seabirds following the collapse of Peruvian anchoveta, their main food (Pauly *et al.* 1989); but in most cases the basic ecosystem had already been profoundly disturbed by natural factors. The collapse of North Sea herring and mackerel was, however, due mainly to fishing which removed some 2 million tons or about one-sixth of the biomass in the area. There was probably a resulting upsurge in small competing species (sandeels, Norway pout and sprat) which may in turn have led to the increase in large predatory gadoids (Cushing 1980), but the evidence is incomplete and circumstantial.

The ultimate genetic threat posed by harvesting and other resource use is the extinction of a species, which results in the complete and (with present technology) irreversible loss of genes or gene combinations, although with the exception of island species, extinction through over-exploitation is rarely recorded (see also 11.2.2.1). Short of extinction, over-exploitation may result in reduction of population size on a local or global scale to a level where inbreeding and loss of genetic diversity become serious problems.

Concern has been expressed in recent years that prolonged fishing, because of its size-selective action, may

alter the genetic structure of the stocks (Policansky 1993; see also Section 13.3.1.1). In large-scale fisheries, where large populations have been depleted from billions to millions, the population may lose a significant proportion of its alleles, which may change the genetic constitution of a population dramatically (Ryman *et al.* 1994). The immediate biological implications of dramatic losses of alleles are unclear, but an organism’s potential to survive and adapt to future environments is dependent on allelic diversity.

The ecological effect of changed genetics may influence life-history patterns, including age and size at maturity and reproductive investment of species (Ricker 1981; Law and Grey 1989; Ryman 1991; Hindar *et al.* 1991; Rijnsdorp 1991; Jorgensen 1992; Stokes *et al.* 1993). For example, selective harvesting of different species of Pacific salmon (*Oncorhynchus* spp.) on the west coast of North America has resulted in decreased growth rate and age at maturity over the past 60 years (Ricker 1981). However, in any particular situation it is difficult to foresee the nature and magnitude of the genetic changes caused by differential use (Hindar *et al.* 1991), and the ecological effects of this (Nelson and Soulé 1987). The biology of extinctions is discussed in greater detail in Section 4.4.

Figure 11.2-3: A classification of agricultural systems on the basis of their biological diversity and complexity. The vertical axis grades systems in relation to species richness of the productive biota, while the horizontal axis represents the complexity of the farming system structure in terms of the diversity of the different types of production system (Swift and Anderson 1993).

11.2.2.2 Expansion of agriculture, forestry and aquaculture

11.2.2.2.1 Introduction. Until this century, farmers and pastoralists bred and maintained a tremendous diversity of crop and livestock varieties around the world. But on-farm diversity is shrinking fast due to modern plant-breeding programmes and the resulting productivity gains achieved by planting comparatively fewer varieties of crops that respond better to water, fertilizers and pesticides. Swift and Anderson (1993) have classified agricultural systems on the basis of their biological diversity and complexity (Figure 11.2-3). The current dominance of intensive cereal production has led to a significant reduction in the number of species and of production systems.

Biswas (1994) has reviewed the impact of modern agriculture on the environment, concluding that the resources necessary for food production have deteriorated since 1962. Modern intensive agriculture has had an adverse impact on the physical environment through the degradation of land, the depletion of water resources and the loss of genetic diversity. Between 1952 and 1989, the area of cereals harvested increased from 616 844 000 ha to 704 732 000 ha, an increase of 14%. However, the yield increased from 1233 kg/ha to 2646 kg/ha, an increase of 114% (FAO 1990a), mostly due to increased use of fertilizers and pesticides. The modern systems have developed in close collaboration with the use of pesticides in a bewildering variety (Mannion 1991) (Box 11.2-3), the impacts of which are discussed in 11.2.2.5.

As a result of changing conditions in agricultural fields, many species of wild birds which had adapted to previous environmental conditions are undergoing significant population declines. Fuller *et al.* (1991) have demonstrated that many of the British farmland birds have undergone startling declines since 1970 as agricultural patterns have changed to remove hedgerows and farm larger contiguous areas (Table 11.2-2), and in conjunction with the loss of roadside verges, pits and ponds, this loss of habitat has contributed substantially to the decrease in biodiversity in Europe over the last century (Agger and Brandt 1988). In addition, there is evidence that, in general, species diversity and abundance are lower on farms using chemicals as fertilizers and pesticides than on farms using organic farming techniques.

Agricultural activities have three kinds of impact on biodiversity: (1) on the natural ecosystems (and their constituent species) within or in place of habitats or areas where they are conducted; (2) on the genetic variability of the cultivated or husbanded species themselves; and (3) through chemical pollution (covered in 11.2.2.5). The degree of impact can range from extinction to increase in population. Over-exploitation may result in reduction of population size to a level where inbreeding and loss of genetic diversity become serious problems. And some

species, notably those that benefit from the agricultural plants, may increase to the level at which they become pests. Some domesticated plants and animals may have greatly increased genetic diversity (at least historically). We assess below the relative impacts of traditional and modern/commercial agriculture on other habitats and on genetic variability.

11.2.2.2.2 *Traditional cultivation.* At the level of intra-species genetic variation, traditional agriculture has been tremendously successful in enhancing biodiversity. Within

Table 11.2-2: *Decline in population of farmland birds in Britain between 1970 and 1988 as shown by the Common Birds Census (from data in Fuller et al. 1991).*

Species	Percentage decline
Corn bunting	69

Blackbird	28

200 regularly cultivated plant species (WCMC 1992), very large genetic diversification has occurred in farming communities over the centuries. No aggregate figures appear to be available, but some indication can be had from the individual crop and country examples given below.

For farmers practising low-input agriculture, the maintenance of species and genetic diversity in fields is an effective strategy to create a stable system of conservation. Cultivated crops often intercross with their wild or weedy relatives growing in the field or in nearby fields, resulting in new characteristics. This has been observed for ensete (*Ensete ventricosum*) in central and southern Ethiopia. Farmers have exploited this system of interbreeding to adapt plants to changing agro-ecological realities. Strategies of intercropping and cropping with varietal mixtures may result in accidental crosses between the varieties, thereby promoting introgression and new genetic combinations. Bayush (1991) reports that farming communities in southern Ethiopia actively manage germplasm through artificial selection. It is believed that the different characteristics of plants within the brassicas, such as *Brassica carinata* (Ethiopian mustard) and

Brassica nigra (black mustard), arose on farms in which mixtures of these two species were planted. Also, coffee growers often preserve a diversity of local varieties in small areas alongside the more uniform coffee blight disease-resistant line which is distributed by the coffee improvement projects in Ethiopia (Worede and Mekbib 1993; Boef *et al.* 1993).

Traditional agriculture has been characterized not only by high intra-species diversity, but also by the use of a wide variety of crop species within the same system. In India, one species of mango, *Mangifera indica*, has been diversified into over 1000 varieties; and one species of rice, *Oryza sativa*, has over 50 000 varieties (IIPA 1995). In Java, small farmers cultivate 607 crop species in their gardens, with an overall species diversity comparable to deciduous tropical forest (Dover and Talbot 1987). This immense diversification within and between crop species was not accidental, but often carefully developed by farming communities.

The perception that agriculture has negative impacts on natural biodiversity is widespread, but not necessarily true where people have carefully adapted their farming and harvesting techniques to their environment. In the plains of Uttara Kannada (southern India), dominated by erstwhile shifting cultivators, under traditional management about 6% of the land was maintained under sacred groves. The mosaic of shifting cultivation sites, pastures, sacred groves and secondary forests in different stages of vegetational succession enhanced landscape heterogeneity and had been responsible for the abundant wildlife, including game animals and birds, which the local communities hunted for subsistence in the pre- and early colonial period (Chandran and Gadgil 1993). In the Amazon, there is often little distinction between cultivated and wild species, nor can a clear boundary be drawn between fields and fallow or between fallow and forest. Yet effects of indigenous cultivation are far-reaching and have substantial impacts on levels of biodiversity. Posey (1982) found that while routinely scavenging through the forest, the Kayapo Indians of Brazilian Amazonia gathered dozens of plants, carried them back to the forest campsites or trails, and replanted them in natural forest clearings. Such plants included several types of tubers, beans and other food plants. Such ‘forest fields’ are always located near streams, but even in the savannah, where patches of forest are scattered, areas where collected plants have been replanted form useful food depots for the Kayapo. This age-old pattern has had profound effects on the distribution of plants in the forest and has been an essential contributor to the current high levels of biodiversity in Amazonia.

Other studies have shown that moderate levels of human use tend to increase local biodiversity, by opening up new niches, providing new food or shelter sites, and diversifying the micro-habitats. Janzen (1987) reports that a

tropical forest that has had some crop production has a larger number of insect species than a primary forest. A study of two oases in the Sonoran Desert on either side of the Mexico–United States border found that the customary land-use practices of Papago farmers on the Mexican side of the border contributed to the biodiversity of the oases, while the protection from human use of an oasis 54 km to the northwest, within the Organpipe Cactus National Monument, resulted in a decline in the species diversity over a 25-year period (Nabhan *et al.* 1982). Saldarriaga *et al.* (1988) found that old secondary forest has greater species diversity than mature primary forest, with each 0.03 ha plot in 14-year-old secondary forest having 56 species, while plots of the same size in 30-year-old secondary forest had 77 species, 80-year-old secondary forest had 79 species, and mature primary forest had just 66 species.

Kappelle *et al.* (1995) studied changes in terrestrial vascular plant diversity along a successional gradient in a Costa Rican upper montane *Quercus* forest, finding that early secondary forest had 145 species of plants, late secondary forest had 130 species, and primary forest had just 96 species. They conclude that montane secondary forests can play a major role in the conservation of tropical montane vegetation, since they harbour a wealth of plant species which are becoming threatened in their original habitats up-slope. This is especially true for tropical alpine (*páramo*) and sub-alpine herb species that flourish in the early stages of montane secondary forest that recover from clearing and subsequent grazing. Moreover, their presence enhances the establishment of later successional species which are responsible for the success of the forest recovery process. In fact, secondary forests in upper montane Costa Rica can be as diverse as neotropical lowlands.

Such findings have also been observed in the case of traditional shifting cultivation in Asia (Ramakrishnan 1992; Wharton 1968). Forest clearings established by shifting cultivation in Southeast Asia provide the major habitat for

most of the region’s large herbivores, especially wild cattle (Wharton 1968). In the Western Ghats district of Uttara Kannada, the nomadic shifting cultivators seldom came back to recultivate the fallow, which resulted in an enormous growth of secondary forests, a mixture of climax evergreens and deciduous timber trees such as teak (*Tectona grandis*) and rosewood (*Dalbergia latifolia*) (Chandran 1992). The prohibition of shifting cultivation in Uttara Kannada by the close of the nineteenth century and the simultaneous extraction of deciduous hardwoods resulted in quick elimination of species such as teak, prompting the Indian Forest Department to clear-fell natural forests and raise teak monocultures, with disastrous impacts on biodiversity.

Traditional agriculture has also played an important role in conserving genetic diversity by ensuring the perpetuity of certain species. A well-known example is that of the recently discovered perennial corn, *Zea diploperennis*, a secondary species that grows in abandoned cornfields. To protect the species, the local slash-and-burn techniques of traditional agriculture may be the most efficient way to provide the habitat that it requires. Without all the human cultural practices that go with the habitat, the species could be lost (Gómez-Pompa and Kaus 1992).

Traditional pastoralists have often tended to foster biodiversity, in both plants and animals. Many pastoral societies have developed elaborate protection systems for the preservation of the vegetational resources of their grazing areas (Shoup 1990), though their impact on wild mammals remains controversial (Table 11.2-3). Pastoralists have deliberately bred livestock to meet different needs and conditions. For example, at least a dozen breeds of camel are known in the Sudan alone (Köhler-Rollefson 1993). However, the wealthier sectors of society in Sudan are now accumulating large livestock holdings through purchase of animals from different tribal groups, with the resulting cross-breeding making camels into one generic type. It is

Table 11.2-3: Alternative viewpoints on the influence of pastoralism on wild mammals (after Happold 1995).

Viewpoint 1 (Brown 1971; Poins 1992)	Viewpoint 2 (Homewood and Rodgers 1987)
Cattle compete with mammals for forage.	Cattle and mammals can coexist because of niche separation.
Cattle cannot coexist with wild mammals.	Cattle can coexist with wild mammals.
Too many cattle cause ecological degradation.	Cattle do not cause long-term degradation, even though pastures may look overgrazed at the end of the dry season.
The number of pastoralists must be limited to conserve the pastoral way of life.	The number of pastoralists can increase (within limits) without adverse effects.

clear that breeds of domestic animals are not simply biological taxa, but rather represent the outcome of social processes; they are therefore unlikely to survive outside the social contexts and production systems that formed them.

Ironically, the gradual disappearance of indigenous breeds that are able to exploit the vegetational resources of extreme environments, such as deserts and other uncultivable lands, seriously affects the capacity of human society to inhabit large areas of the globe. The loss of these hardy animal breeds therefore means a reduction in the area of human habitat (Köhler-Rollefson 1993). Pastoral societies therefore contribute significantly to the maintenance of biodiversity in domesticated animals and help keep otherwise barren tracts of land habitable for humans.

Although many examples of traditional management are positive, many cases of mismanagement can be found as well. Linares (1976) describes archaeological sites at Cerro Brujo which represent a 20–30 year occupation about a millennium ago, indicating that the residents significantly over-exploited their habitat and then moved on to a new area. Perhaps at that time, this system was sustainable in that over-used habitats were able to restore themselves and migration was possible.

Many agricultural areas can be considered ‘semi-natural communities’, defined as plant and animal communities composed of species that are indigenous and/or wild in the region, but where the development and maintenance of the communities requires direct or indirect human impact. This human impact can be through a variety of practices linked to agriculture, such as forest clearing, burning, grazing by domestic animals, and/or mowing. The long-term persistence of these activities is essential to maintaining the biodiversity of these systems. European examples of semi-natural vegetation include most lowland heathlands and grasslands, and many woodlands and shrublands that have been affected by burning and grazing. On the other hand, natural grasslands and heathlands in Europe are shaped mainly by climatic and edaphic factors and include alpine grasslands and heathlands above the treeline and communities affected by periodic flooding along freshwater and marine shores. Many European grasslands have their origins in early prehistoric times, some 6000 years ago (Berglund *et al.* 1991) or even earlier (Bush and Flenley 1987). The biologically important Atlantic heathlands along the Atlantic coasts in Western Europe (Gimingham and de Smidt 1983) were developed during the Early Iron Age, c. 2000 years ago (Berglund 1969; Odgaard 1994). Recent investigations indicate that some moorlands of Western Europe, the blanket bogs, might have been initiated as early as the Mesolithic, around 7700 BP, by human activity of burning and grazing (Caseldine and Hatton 1993). These heathlands and grasslands are today threatened ecosystems that harbour a number of endangered plant and animal species and act as refuges of

biodiversity (Oostermeijer *et al.* 1994). The threats are mainly changes in land management, including cessation of grazing or mowing (Stevenson and Thompson 1993).

For semi-natural grasslands on limestone bedrock and calcareous soils, plant biodiversity reaches very high levels. Among the highest species richness ever recorded of field layer species (expressed as number of vascular plant species per unit area) is one reported from semi-natural meadows on limestone bedrock in South Estonia, with 63 species per square metre (Kull and Zobel 1991). Semi-natural grasslands are definitely European hotspots of biodiversity; in the absence of active management these semi-natural grasslands and heathlands revert by natural succession to woodlands and forests, and the species richness of vascular plants declines (Londo 1990).

Furthermore, indications are that the long-term existence of semi-natural communities has allowed the development of subspecies (and maybe even new species) with adaptations to the specific ecological conditions prevailing in a grazed or mowed grass-sward (Reinhammar 1995; Olsson *et al.* 1995).

11.2.2.2.3 Modern cultivation. Overwhelming evidence leads to the conclusion that modern commercial agriculture has had a direct negative impact on biodiversity at all levels: ecosystem, species and genetic; and on both natural and domesticated diversity. Agriculture may be one of the most important causes of pollution, by the production of sediments, by the generation of chemical wastes, or by the use of pesticides (Goudie 1993), and the runoff of organic wastes and inorganic fertilizers inflicts significant damage on aquatic ecosystems.

On the other hand, modern intensive agriculture has enabled substantial human populations to be fed, without resorting to extensive forms of agriculture which might cause even worse losses of biodiversity. Current information does not allow any general conclusion on this point, but further examination of the issues involved may lead to improved understanding.

At the level of ecosystems, commercial agriculture has led to considerable homogenization of the landscape. Surface irrigation schemes, for instance, transform a complex mosaic of micro-habitats into a uniform agricultural landscape, favouring relatively few crop species and varieties. In the process, micro-habitats such as hedgerows, fallow, bushy growth, tree groves and others, which harbour considerable biodiversity, are lost. Irrigation has been used by agriculturalists for thousands of years, dating back to the first major civilizations of Mesopotamia, and it is believed that irrigation on a large scale allowed the development of urban cultures by increasing the carrying capacity of the land, with a number of profound social consequences (Wittfogel 1957). However, the gradual salinization of the land which resulted, along with other unsustainable land practices, eventually lead to the

downfall of the Mesopotamian civilization of Sumer (Barnaby 1988).

Irrigation has continued to play a role in agricultural activities world-wide and WRI (1994) estimates that it is the largest consumer of fresh water on a global scale, consuming 2.5 times more than industry and accounting for 63% of water withdrawal globally (WRI 1990). Over the last few decades it has played a vital role in the dramatic increase in food production. White (1994), for example, estimated that 55% of the world's rice areas rely on irrigation. The total area of irrigated cropland in the late 1980s was 230 million ha representing 15% of the cropland world-wide and 31% of cropland in Asia (WRI 1990).

Although figures are conflicting, an authoritative estimate suggests that 2 million hectares per year are lost through salinization (FAO estimate quoted by Döös 1994), the same problem that afflicted early Mesopotamian efforts at large-scale irrigation. It seems likely that increasing dependence on irrigation in food production could exacerbate this problem. In its extreme form it results in the death of vegetation through toxicity and poor soil structure, creating bare ground which then becomes eroded by wind and water. For example, one of the most threatened ecosystems of the Indian subcontinent is the tropical thorn forest. The inception of canal irrigation in the last century and further new settlement and development of underground water resources and increasing trends toward waterlogging, salinity and desertification have now pushed natural tropical thorn forest communities to the verge of extinction (Khan 1994) (Box 11.2-4).

The evolution of crops over the past 10 000 years has been affected by both natural and artificial selection, the latter involving isolation of stocks followed by migration and seed exchanges; the resultant hybridization and recombination of genes has undoubtedly added to the genetic diversity of crop species. However, modern cultivation techniques are signalling the end of this period of diversification. The major threat to traditional varieties in the developing world is the process of agricultural modernization. In 20 years, a few modern high-yield varieties (HYVs) have replaced ancient crop varieties or 'landraces' as part of international and national efforts to develop agriculture. Preliminary assessments of genetic erosion in Mexico and Peru indicate several trends that may be generalized to most crops in the region (Brush 1991; Brush *et al.* 1992; Bellon 1991; Bellon and Brush 1994):

- Genetic erosion is occurring because farmers are changing their farming systems, pushed by social, economic and technical forces.
- The pattern and rate of adoption of HYVs is very uneven across geographic regions.

Box 11.2-4: Agricultural intensification and biodiversity in the Aral Sea.

A tragic example of how agricultural intensification can go wrong is observed in the Aral Sea, the largest body of water between the Caspian and the Pacific. Vast new irrigation systems, including the 1100 km Karakum Canal through southern Turkmenistan, led to the draining of the Amu Darya and Syr Darya rivers, causing the Aral Sea to shrink by over half and lose more than two-thirds of its volume since 1960. Its largest city is now 100 km from the shore. The loss of biodiversity has been profound; its waters formerly supported 24 species of fish, but now support none, and its 60 000 fishermen are unemployed. The former seabed is now a salt desert swept by the prevailing north wind, which dumps between 40 and 150 million tons of sand and salt on the precious fertile land of the Amu Darya delta each year. The problems are made worse by the use of pesticides and chemical fertilizers which are considered necessary to maintain yields of cotton, but which accumulated in the sediments of the Aral Sea, and are now turned into dust and carried to the surrounding lands (Ellis 1990; Kotlyakov 1991; Precoda 1991).

- As adoption of HYVs occurs, farmers tend to subdivide their farming systems into commercial sectors mostly devoted to HYVs and subsistence sectors where they still grow native varieties.
- Greatest losses of traditional varieties have occurred in lowland valleys close to urban centres and markets.
- The least genetic erosion occurs in higher zones (especially mountain areas) distant from urban centres and markets.

In general, diversity of crop genetic resources is affected by the following factors which both promote and constrain genetic change:

- Changes in numbers of and distribution of human populations.
- National and international crop improvement and extension programmes.
- Changes in consumption patterns in urban and rural populations.
- Increases in demand from urban markets.
- Improvements in transportation and communication systems.

- General factors in the agricultural economy such as human capital, labour, credit, tenure, and the availability of fertilizers, pesticides and irrigation.
- Development aid programmes.

Three decades of the Green Revolution in India have led to an enormous loss of biodiversity, though the exact dimensions are still not assessed. Some idea of the loss can be gauged by the fact that a handful of HYVs are now grown on over 70% of the rice land and 90% of the wheat land; in the Godavari district of Andhra Pradesh, an estimated 95% of rice varieties have been lost. Possibly thousands of varieties of rice, cotton, minor millet, pulses, and other crops are no longer in use in farmers' fields (Shiva 1991; Kothari 1994a). This loss of crop diversity extends globally to most crop species, including wheat and maize which, along with rice, supply half the world's caloric intake (Huxley 1984).

The loss of genetic diversity also occurs with animal domestication where a few highly productive breeds are transported world-wide, displacing and eventually resulting in the extinction of local breeds. The simplification of agricultural systems has severely affected the genetic diversity of domestic species of animals, with some 27% of the 1400 recorded breeds with population data threatened with extinction (Loftus and Scherf 1993) (Table 11.2-4). Genetic improvement has been used with particular intensity in the developed regions of Europe and North America during the second half of the twentieth century, where it has caused a marked decline in the numbers of traditional breeds and a preference for a few highly productive breeds serving the modern markets for milk and meat products. This decline in indigenous breeds and their replacement by a few highly favoured breeds has not yet taken place so thoroughly in the developing regions, owing to the greater need for adaptive traits in the tropics. However, genetic diversity in domestic livestock species can be expected to decline in the tropics as modern management techniques are introduced which modify the animals' environment and permit the use of less adapted breeds. India, for example, has a history of three decades of modern livestock breeding; an estimated 50% of indigenous goat breeds, 20% of indigenous cattle breeds, and 30% of the indigenous sheep breeds are today threatened (Balain 1992). The decline of local livestock diversity has perhaps been greatest in poultry; an estimated 80% of the total population in use is now of exotic breeds.

These various races/breeds along with their wild counterparts form the genetic base which plant and animal breeders use in developing their high-yielding varieties; their loss thus threatens the very building blocks of our modern agricultural system.

On the other hand, the expansion of agriculture seems inevitable. As Thomas Jefferson (quoted by McMillen

1981) said over 200 years ago, 'Whenever there are in any country uncultivated lands and unemployed poor, it is clear that the laws of property have been so far extended as to violate natural right. The earth is given as a common stock for man to labour and live on.' Two centuries later, naturalists might give wilderness itself more standing than Jefferson did. Nevertheless, even today parents of hungry children will not long hesitate to cross a boundary drawn around uncultivated land by absentee law-givers. What might be called Jefferson's Law of Property states that cropland will expand to match the product of population times diet divided by yield – regardless of legalities. Abundant harvest from cultivated land is the essential element for preserving the biodiversity on other, uncultivated land.

From AD 1700 until the middle of this century, agriculture grew more extensive, expanding global cropland per capita to about 0.5 ha. During recent decades, however, cropland per capita has fallen to 0.3 ha. Given the simultaneous improvement in diet and Jefferson's Law, higher yields – not rising population – caused the declining cropland per capita with the opportunity to preserve natural biodiversity on other, uncultivated land (Waggoner 1994).

11.2.2.2.4 Fisheries. Aquatic ecosystems, covering two-thirds of our planet's surface, have always been an important source of human food. All aquatic populations show biomass fluctuations: biomass increases with recruitment and individual growth, and decreases with mortality. The loss in biomass can be divided into natural mortality (predation, starvation, disease, etc.) and fishing mortality (human harvest).

WRI (1994) concluded that stock depletion in marine fisheries does not necessarily lead to endangered/extinct species, although it has other undesirable effects (social and economic). No case of overfishing leading to the extinction of a species has ever been documented. More insidious effects, which are difficult to quantify, include the effects

Table 11.2-4: Domestic breeds at risk (Loftus and Scherf 1993).

Total	2719	1433	390

1. Estimated from breeds with available population data.

of over-exploitation of one species on other species or on whole ecosystems and the genetic effects of overfishing on exploited populations.

Marine and freshwater fisheries do not differ fundamentally; but the freshwater habitats are generally more circumscribed and less hostile as a working environment than the oceans, and are therefore more easily exploited by unsophisticated fishing gears and vessels. Multiple uses of open access freshwaters for fisheries, irrigation, domestic supply, sewage disposal, recreation and navigation leads to relatively frequent conflicts between users. Conversely, many freshwater bodies are privately owned, leaving scope for quite comprehensive management of the resources.

Fisheries can be broadly classified into five categories which form a continuum. Where markets have emerged or been developed, a transition towards more sophisticated, capital intensive systems has often been observed.

- Traditional or subsistence fisheries are those carried out primarily for fulfilling immediate food requirements and the catch is seldom bartered or sold. Examples of sustainable, community-based fishery management include indigenous use of marine mammals in Greenland and North America (Ward 1993), many Pacific Island reef and lagoon fisheries which are governed by elaborate codes of customary laws (Johannes 1981; Ruddle *et al.* 1992), and some invertebrate fisheries in the Caribbean (Smith and Berkes 1991).
- Recreational fisheries, often conducted with rod and line or with spear-guns, are the modern equivalent of traditional fisheries. In Europe and North America, recreational fisheries are of considerable economic importance and, in fresh waters, are usually readily and stringently controlled by licensing.
- Small-scale or artisanal fisheries are conducted on a commercial basis, usually from small vessels (or none at all), operating from beaches or moorings in which the basic operating unit is usually a kin group which markets its own catch. Artisanal fisheries currently provide approximately 25% of the global fish catch and c. 40% of the fish used for human consumption and employ the vast majority of the world's fishers, especially in developing countries. In Africa, the artisanal catch in 1989 accounted for more than 60% of the total domestic catch (Tvedten and Hersoug 1992). Usually a wide array of fishing gear is operated, which will vary according to weather or season, and the catch is composed of a multiplicity of species of fishes and invertebrates. Little is discarded as unsaleable in most developing countries. Although co-management systems have in some cases evolved from community-based management systems and are likely to be a

significant tool in the future, the majority of the world's small-scale fisheries are neither managed nor regulated with any significant effect. In the most overpopulated regions, many of the fishers are landless peasants who have entered the fishery as the resource-of-last-resort. As recent entrants, they are not bound by tradition nor do they have significant experience of the aquatic environment; they are motivated by their immediate need to fish to survive. Many cannot afford to eat the fish that they catch and all must be sold in order to purchase staples such as rice. Under such circumstances the pressure on the resources is very great and fishers are led to use destructive fishing methods such as explosives or poisons which destroy the resource base upon which the fishers depend. This has been termed 'Malthusian over-fishing' (Pauly *et al.* 1989). Moreover, the tendency to copy large-scale western industrial fisheries has yielded a number of failures (Tvedten and Hersoug 1992), and overfishing has become a major problem in small-scale fisheries.

In addition, the artisanal multispecies fisheries, such as operate in most tropical developing countries, can continue to operate after the most desirable species have been drastically reduced in abundance or extinguished locally (Munro and Smith 1984). For example, various species of groupers and snappers have become virtually extinct in Jamaican waters over the past few decades (Munro 1983; Koslow *et al.* 1988) yet the artisanal fishery continues, sustained by price rises for the available species.

- Large-scale or industrial fisheries operate sophisticated fishing vessels which supply centralized marketing systems located in fishing ports. The fishers are seldom involved in the marketing of catches and the crew are usually hired labour. The industrial fisheries of the world have steadily increased their role in world fish production and have, with few exceptions, come to over-exploit the resources upon which they have been based. This has led to economic dislocations, conflicts with artisanal fishers over access to a diminishing resource and drastic changes in the composition of the exploited fish community. The causes of the problems lie primarily in the open access to the resource and the reluctance of authorities to abrogate this 'right'. Additionally, the frequent provision of subsidies to support ailing fisheries, rises in the relative price of fish in response to scarcity, and technological improvements have meant that the best-equipped vessels can still make large short-term profits from a depleted resource. These factors have combined to ensure that most important fish stocks have been fished far beyond sustainable levels in the past decade.

At present, many of the world's largest and oldest fisheries are overfished in the sense that their productivity has been reduced below their potential maximum, sometimes very considerably, by unnecessarily heavy fishing (FAO 1990b). One example is fishing for finfish in the Southern Ocean which began in 1969–70 and for krill in 1972–3. After 15 years of exploitation, most fish stocks around South Georgia and Iles Kerguelen were heavily depleted. Impacts of krill and finfishing on the ecosystem of the Southern Ocean range from endangering recruitment due to the by-catch of juvenile fish in the krill fishery to incidental mortality of birds during longline operations and the entanglement of seals in fragments of discarded or lost fishing gear (Kock 1994). In the North Atlantic, cod populations in West Greenland (Dickson and Brander 1993) and in Labrador and Newfoundland (de Young and Rose 1993) have collapsed, i.e. fallen in abundance by 20 fold or more over a few years, although this has probably been the result of a combination of overfishing and natural causes.

The period from 1950 to 1970 saw the collapse of many of the world's largest fisheries for small pelagic species (Beverton 1990). All but one (Icelandic spring-spawning herring) have recovered, though to varying degrees and at various speeds. Some, like the Icelandic summer-spawning herring (Jakobsson 1992), the Georges Bank herring and the Japanese sardine, are now more abundant than in their former peak. All were heavily fished, especially in the waning years before fishing was stopped. These were species low in the food chain and hence directly dependent on primary productivity (Mann and Lazier 1991). Some are in unstable upwelling areas, e.g. the Peruvian anchoveta (El Niño effect; Pauly *et al.* 1989), and the Californian sardine, where scale deposits show their abundance has altered dramatically over the last 2000 years (Baumgartner *et al.*, 1992). Others are on the meandering edge of a major boundary current, such as the Japanese sardine on the Kuroshio current and Georges Bank herring on the Gulf Stream.

Indiscriminate methods of resource use (e.g. drift-net fisheries) leading to high by-catch mortality can endanger species other than those targeted (Northridge 1991; Mangel 1993). Monofilament drift nets 60 km long and 60 m in depth are used in the South Pacific and the North Pacific, representing a fishing effort in the open ocean that was not previously thought possible. These massive drift nets not only take a huge harvest of target species but also catch non-target species indiscriminately. Elder and Pernetta (1991) report that one fishing trip by 32 Japanese ships using drift nets resulted in the deaths of 50 000 sharks, over

1000 small cetaceans, 52 fur seals and 22 turtles in the process of taking 3 million squid.

'Ghost fishing' refers to discarded or lost fishing nets and traps which continue to catch marine animals (Norse 1993). GESAMP (1990) reported that lost fishing gear was already estimated at 150 000 items world-wide 20 years ago. A 1.6 km long gill net in the North Pacific was found to have 350 seabirds entangled in it. Seals are particularly vulnerable to entanglement: at least 15 of the world's 32 pinniped species have been seen entangled and as many as 10 000 harbour seals (*Phocaena phocaena*) are thought to be lost annually in this way in the Danish North Sea (Vinther 1994). Entanglement kills thousands of northern fur seals in Alaska's Pribilof Islands and it poses an increasingly severe threat to the critically endangered Hawaiian monk seal, even though attempts are made to remove debris from its habitat.

- Aquaculture, whether marine or in fresh waters, is an old tradition, but has been greatly expanded over the past 20–30 years with sophisticated hatchery technologies for mass-rearing of larvae of many species. Technical advances in cultivation systems have enabled operations to be moved progressively into deeper and less protected ocean waters. During 1989–91, average annual aquaculture production of fish and shellfish was c. 12 million tons, and the production is increasing. The largest producers are found in Asia (China, India, Indonesia, Japan, Republic of Korea, Philippines, Thailand), Europe (France, Italy, Norway, Spain) and North America (USA) (WRI 1994). The increase in aquaculture production is rapid and very promising, but industrial fish farming is not without problems and conflicts. For instance, a large number of artificially reared fish escape each year from fish farms into the wild. This can result in the spread of contagious diseases (e.g. furunculosis, bacterial kidney disease), ecological interference with wild populations, and disruption of the genetic structure of wild populations through introgression, genetic drift and unintentional changes in selection regimes (e.g. Egidius *et al.* 1991; Hindar *et al.* 1991; Heggberget *et al.* 1993; Jonsson and Fleming 1993).

The artificial enhancement of natural fish stocks by the release of hatchery-reared fingerlings, also called sea ranching, results in genetic effects on conspecifics which are unpredictable and vary from no detectable effect to complete introgression (Hindar *et al.* 1991). When genetic effects on performance traits have been detected, they appear always to be negative in comparison with unaffected populations. Even when animals from local populations are used as brood stock

in the artificial propagation, the changed selection regime during rearing may change the genetic structure of the recipient population (Ryman and Ståhl 1980; Waples 1991), though the implications of this for biodiversity remain unclear.

11.2.2.2.5 Forestry. Global closed forest is estimated to have covered three million hectares in the early 1980s, roughly evenly split between temperate and tropical areas. In the most authoritative statement on forest status globally, FAO (1993) reports that between 1980 and 1990, an annual average of 15.4 million ha of tropical forests were cleared, amounting to an annual loss of about 0.8% and a total loss over the decade of tropical forests of almost three times the size of France. Alarming as these figures are, it is difficult to determine whether 1970–80 rates of loss were significantly different from the 1970s because FAO used different methodologies in its later assessments. FAO also reports that the area of tropical forest plantations increased from 18 million ha in 1980 to more than 40 million ha in 1990, with about three-quarters found in Asia.

Temperate closed forests are thought to be in a relatively stable state at present, or even showing a slight increase (WRI 1994), although Dudley (1992) warns that this general trend obscures some important regional variations and significant losses in old-growth forests.

Since tropical forests are thought to contain at least 50% of the species of the globe, it is hardly surprising that much attention has been focused on tropical deforestation rates and species extinction.

The documented evidence of species extinction through tropical forest loss is, however, limited and although much controversy surrounds the likely level of extinctions (see Section 4.3 and various papers in Whitmore and Sayer 1992) it is generally agreed that disturbance of forests will

alter the relative frequency of animal and plant species and, where severe, disturbance will cause a ‘commitment to extinction’ although the time to reach the new equilibrium state is unknown (Heywood and Stuart 1992; Reid 1992).

Deforestation has three major effects: habitat loss; habitat fragmentation; and edge effects at the boundary zone between forested and deforested areas (Skole and Tucker 1993). The data presented by these authors on deforestation in the Brazilian Amazon emphasizes the relative importance of the edge effect which may extend 1 km into adjacent forest resulting in a net loss of ‘interior’ plant and animal species in the edge area which may be occupied by a different suite of species (Turner *et al.* 1991). Skole and Tucker’s figures indicate that simply looking at deforested areas alone masks the broader effects: deforestation affected a total of 230 324 km² in their study areas, creating 16 228 km² of isolated forest and an edge effect covering 341 052 km², resulting in a total area affected by deforestation activities of 587 604 km².

Deforestation is a dramatic alteration of habitat but many other levels of degradation, not considered as deforestation, can lead to long-term and perhaps permanent changes in species composition. Logging for international and domestic consumption, although only one of the causes of forest destruction, has proved to be of great importance because it opens up the forest to further encroachment by agricultural settlers, in itself believed to be the single greatest cause of forest destruction (Poore and Sayer 1991; Callister 1992).

Logging activities have both direct and indirect effects on biodiversity. Loggers are usually selective in their choice of species and, although extinction of exploited timber species has not been documented, Oldfield (1988) gives examples of several island endemic species that are on the brink of extinction and lists 41 other timber species

Table 11.2-5: Causes of tree mortality during logging (from Johns 1992).

Percentage Loss of trees (>30 cm girth)					
	Ponta da Castanha, Brazil	Nigeria	S. Tekam, Malaysia	S. Pagai, Malaysia	G. Tebu, Malaysia
Killed					
Timber trees	0.6	1	3	8	10
Destroyed during construction of access roads and landing sites, etc.	60.4	25	8	46	55
Destroyed during felling and dragging			39		
Remaining	39	74	49	46	35

which are considered endangered as a result of their exploitation. Kemp (1992) stresses the importance of losses in genetic diversity in target species as a result of selective logging. The removal of timber trees is only a relatively minor consequence of logging and Johns (1992) documents the much higher losses of non-target trees as a result of access roads, landing sites and inadvertent destruction during felling and dragging (Table 11.2-5).

It is difficult to generalize on the effects of logging since so much depends on the intensity of logging and on the response of different animal and plant species to disturbance. Certain groups are highly sensitive to disturbance (e.g. amphibians, Johns 1985; termites, Collins 1980) and tend to disappear or show a reduction in species diversity after logging. Diversity also declines in forest avifauna that are specialized feeders (Johns 1985) and for many mammals there is a marked decline in abundance (Collins *et al.* 1991). However, some species withstand the effects of logging well (e.g. some primates) and of course plant diversity may increase soon after logging activities as a result of growth of pioneer species which germinate quickly to fill the gaps created by logging, thus altering the

Table 11.2-6: Proportion of old growth forest remaining in selected temperate forest countries (from Dudley 1992).

1. Australian figures vary widely. The Resource Assessment Commission, in their massive 1991 study, concluded that around half of the original forest resource had been felled and that 42% of forest was unlogged, so a figure of 21% has been suggested according to their calculations. However, WRI calculated just 5%, using figures from Wells *et al.* (1984).

species composition of the area (Johns 1985). Johns (1992) documents the successful recolonization of logged areas, although this may take many years and depends on there being a source of colonists in nearby unlogged forest (thus highlighting the importance of unlogged ‘refuges’ in managed tropical forests).

Totally protected areas cover only about 5% of the tropical forest biome and are therefore not sufficient to ensure the conservation of biological diversity (Sayer and Wegge 1992) but there is a broad consensus that it is technically possible to manage tropical forests for timber and other forest products and maintain considerable biological biodiversity if there is a political will to do so.

Temperate forests account for around 50% of global forest cover but, because of their lower diversity when compared with tropical forests, are generally not the focus of so much attention. Although their current status is considered stable this masks significant losses, particularly in Asia, and also the continuing loss of old growth temperate forest globally (Dudley 1992). Old growth forests, although not as diverse as their tropical counterparts, are frequently the richest habitats in the regions in which they occur and their rate of loss in some areas is faster than the loss of tropical forest in most countries (Dudley 1992). In addition, some temperate forests represent areas of biological diversity of global significance with high levels of endemism (for example in the old growth forests of New Zealand and Chile).

In western Europe, old growth forest represents less than 1% of total forest area, large-scale deforestation having taken place in historical times, and probably only Canada and New Zealand among the temperate countries retain more than 20% of total forest area as old growth forest (Table 11.2-6).

Trends similar to those discussed for agriculture are transforming diverse forest ecosystems into high-yielding monocultural tree plantations – some of which now resemble a field of maize as much as a natural forest – and even fewer tree genes than crop genes have been preserved off-site as an insurance policy against disease and pests (Chaney and Basbous 1978; MacKenzie 1986; Vitousek *et al.* 1987; Janzen 1988; Reid and Miller 1989; Schneider 1989; Thorsell 1990).

Although available figures show considerable variation, Sawyer (1993) estimates that there are currently 100 – 135 million ha of plantations world-wide roughly divided 25–75% tropical – temperate. As more plantations are developed to help alleviate the fuelwood crisis in certain countries, relatively more plantations will be developed in tropical areas. Plantations are highly variable: they may be monoculture or mixed; composed of indigenous or exotic species; large-scale or small-scale; structurally complex or simple. These parameters have important effects on their levels of biodiversity.

Table11.2-7: Habitat and human disturbance by continent (after Hannah et al. 1994).

Continent	Total Area(km ²)	Undisturbed %	Partially Disturbed %	Human Dominated %
Europe	5 759 321	15.6	19.6	64.9
Asia	53 311 557	42.2	29.1	28.7
Africa	33 985 316	48.9	35.8	15.4
North America	26 179 907	56.3	18.8	24.9
South America	20 120 346	62.5	22.5	15.1

Antarctica	13 208 983	100.0	0.0	0.0
World total	162 052 691	51.9	24.2	23.9
World total reduced by area of rock, ice and barren land	134 904 471	27.0	36.7	36.3

Plantation forestry often creates artificially homogenous forests with one or a few tree species with individuals of the same size and age, like the cultivated monocultures of agriculture. Some forest plantations may use indigenous tree species, which will retain some of the natural biodiversity of the area through predators, parasites and symbionts of the tree species. But compared to a diverse community of trees, the plantation monoculture will simplify the other components of the ecosystem, not least the structure, fauna and flora of the soil. When industrial tree plantations are based on exogenous species, much of the native biodiversity is inevitably lost, especially through the active suppression of competing species, parasites, etc., through spraying with biocides or other actions (Maser 1988). Although plantations can be managed to maximize species diversity they are unlikely to attain the biodiversity levels of natural forest and should not be regarded as an alternative to natural forests but rather as complementary to them.

11.2.2.3 Habitat loss and fragmentation

Habitat destruction is widely considered the most pervasive anthropogenic cause of the loss of biodiversity (Brown 1985; Wilson 1985; Myers 1988). McCloskey and Spalding (1989) produced a quantitative analysis of the global distribution of ‘undisturbed ecosystems’. However, they defined ‘undisturbed’ simply in terms of roadless areas in chunks of greater than 400 000 ha. Hannah *et al.* (1994) carried this effort further and reduced its mapping units to 100 000 ha (Table 11.2-7). They concluded that 73% of the world’s land surface other than rock, ice, and barren land is either human-dominated (36.3%) or partially disturbed (36.7%), while 27% is ‘undisturbed’. However, it is clear that no part of the world can be considered truly ‘undisturbed’. The world’s habitats have been so

significantly modified by human action that such terms as ‘native ecosystem’, ‘undisturbed’, or ‘virgin forest’ are of little practical utility (Thomas 1956; Balée 1985; Roosevelt 1989; Turner *et al.* 1990; Gómez-Pompa and Kaus, 1992; Meyer and Turner 1992; Fairhead and Leach 1993; McNeely 1994). MacKinnon and MacKinnon (1986a, b) estimate that 65% of the original ecosystems south of the Sahara have been subject to major ecological disturbance, and 68% of the natural habitat has been lost in the Indo-Malayan nations (Table 11.2-8). In freshwater ecosystems, dams have destroyed large sections of river and stream habitat. In marine ecosystems, coastal development has wiped out reef and nearshore communities.

Human impacts on habitats take two main forms: conversion from one habitat type to another; and modification of conditions within a habitat type (Meyer and Turner 1992). No general assessment of human impacts on habitats is available at any detailed scale, but as a broad-scale surrogate, land cover is frequently used by various global assessments (e.g. WRI 1994). Conversion of one category of land cover to another is better documented and more readily monitored than modification within a category, but most global classifications are so broad that they mask a number of important forms of land-cover modification, such as forest thinning, replacement of old forest with tree plantations, intensification of cultivation, and severe overgrazing of rangelands. This problem is especially apparent in the UN Food and Agriculture Organization’s *Production Yearbooks*, which use four broad classes: forest/woodland; permanent pasture; cultivation; and ‘other lands’. Further, the statistics contained are simply those reported by FAO member states, so quality is widely variable and sometimes politically motivated. An alternative approach is based on climate modelling and carbon storage (Matthews 1983;

Richards 1990). Such approaches deal with ecosystem modification as well as conversion, but the categories used are still extremely broad. While issues of data quality and comparability make global-scale assessments of land-use change difficult, Meyer and Turner (1992) have presented a useful summary of available information (Table 11.2-9).

Forests are the most species-rich terrestrial habitats (Maser 1988; Whitmore and Sayer 1992), but assessing human impacts on global forest cover is made more difficult by multiple definitions of ‘forest’. Meyer and Turner (1992) summarize available information by estimating that about 29 million km², or 21% of the world’s land area, is covered in closed forest, while ‘open woodland’, an ill-defined category that overlaps significantly with other standard cover types, adds about 18 million km² to the total. The estimated original 62 million km² of forest and woodland in pre-agricultural times has been reduced by 9 million km², of which 7 million represents loss of closed forest, a net global decrease of about 15%. While estimates of contemporary forest change vary considerably and are hampered by problems of data, definition, and method (Myers 1989; WRI 1994), the broad pattern is one of stability or even net gain in temperate

Table 11.2-8: Human impact on habitats: conversion.

countries and rapid loss in the developing tropics, adding up to an annual net global loss of 100 000–200 0000 km² in recent years. Deforestation affects biodiversity through destruction of habitat, isolation of fragments of formerly contiguous habitat, edge effects within a boundary zone between forest and deforested areas (Skole and Tucker 1993), and a variety of other mechanisms (Grainger 1992) (Box 11.2-5). In the boundary zone, edge effects lead to a net loss of plant and animal species through greater exposure to winds, increased micro-meteorological differences over short distances, and easier access for livestock, other non-forest animals, and hunters.

Brazil has the largest remaining area of tropical forest, but it too is under human pressure. Skole and Tucker (1993) used Landsat satellite imagery covering the entire forested portion of the Brazilian Amazon Basin to measure habitat loss and fragmentation in 1978 and 1988. They found that deforestation increased from 78 000 km² in 1978 to 230 000 km² in 1988, while habitats severely affected with respect to biodiversity increased from 200 000 to 588 000 km². Although this rate of deforestation is lower than other estimates, the effect on biological diversity is greater than just the loss of forest. Skole and Tucker found that the geometry of deforestation is critical to the estimation of forest fragmentation and the edge effect. If 100 km² of tropical deforestation occurs as a 10 km × 10 km² block and it is assumed that the edge effect is 1 km, the total area affected is about 143 km². But if the 100 km² of deforestation is distributed as 10 strips, each 10 km × 1 km, the affected area is about 350 km². They found that the largest contributor to negative effects on biological diversity was the 1 km edge effect from adjacent areas of deforestation, while isolation of forest patches was not a large contributor. While the rate of deforestation averaged about 15 000 km² per year in the Brazilian Amazon from 1978 to 1988, the rate of habitat fragmentation and degradation was about 38 000 km² per year.

The distribution and extent of grassland is controlled by

climate, soil and fire, the last of which represents asinificant long-standing human impact (Hough 1926; Thomas 1956). The world area of grassland and pasture in 1700 is estimated at 68.6 million km², a figure that is nearly identical with that of today (Richards 1990). Factors affecting the global area of grassland have thus maintained a rough balance over the past 300 years, with loss through

Box 11.2-5: The consequences of tropical deforestation for biodiversity (modified after Grainger 1992).

1. Reduced diversity of species and genes
 - (a) Species extinctions
 - (b) Reduced capacity to breed improved crop varieties
 - (c) Inability to make some plants economic crops
 - (d) Threat to production of minor forest products
2. Changes affecting local and regional ecosystems
 - (a) Soil degradation
 - (b) Changes in water flows from catchments
 - (c) Changes in buffering of water flows by wetland forests
 - (d) Increased sedimentation of rivers, reservoirs, etc.
 - (e) Possible changes in rainfall characteristics
3. Changes affecting the global ecosystem
 - (a) Reduction in carbon stored in the terrestrial biota
 - (b) Increase in carbon dioxide content of the atmosphere
 - (c) Changes in global temperature and rainfall patterns by greenhouse effects
 - (d) Other changes in global climate due to changes in land surface processes

Table 11.2-10: Extent of desertification in rangelands within the drylands of the world (thousand ha) (from UNEP 1991).

Continent	Slight to none	Moderate	Severe	Very severe	Total moderate, severe and very severe	Percentage desertified
Africa	347 265	273 615	716 210	5 255	995 080	74
Asia	383 630	485 221	691 602	10 787	1,187 610	75

South America	93 147	88 007	184 431	15 316	297 754	76

conversion to cropland being balanced by gain through deforestation. The global pattern has been significant grassland decrease in Europe, North America, and Southeast Asia, matched by increases in Latin America and tropical Africa (Meyer and Turner 1992).

It is difficult to generalize on the effect of these changes on grassland biodiversity since it is such a varied habitat with important distinctions between wet and dry grasslands, acid, base and neutral grasslands, etc. However, at least within Europe, a broad generalization is that the wildlife value of grasslands is likely to diminish as the intensity of production increases. Thus drainage, use of fertilizers and pesticides, greater densities of livestock and conversion from hay-making to silage are all likely to reduce biodiversity. In Europe the general consensus is that unimproved, extensively managed grasslands have declined sharply in recent decades as a result of more intensive management, conversion to arable land and a range of other uses (Baldock 1990). While difficult to generalize on the overall losses in biodiversity, the 164 species of dry grassland plant species threatened with extinction in Germany (Wolking and Plank 1981) and the fact that grassland specialists make up 40% of the bird species listed as vulnerable in Europe (Devillers 1988) attest to the probable effects.

Grasslands are subject to alteration to desert-like conditions under excessive human pressure. The 1977 UN Conference on Desertification identified 6% of the world's area as 'man-made deserts', with a quarter of the world's surface threatened by desertification. The annual degradation of land to 'desert-like conditions' was estimated by UNEP as 60 000 km² and the area annually reduced to zero or negative net economic productivity amounted to 200 000 km² (Rapp 1977; Mabbutt 1985) (Table 11.2-10).

It is currently believed that many tropical and subtropical grasslands are maintained by fire. A significant component in this dynamic is human-induced fires that increase fire frequency. Because of the long history of fire use, human

impact has probably contributed to the present ecosystem structure and function. Recent views on the prairies in North America interpret them in part as semi-natural ecosystems maintained by grazing of wild animals and by fires set by the native Americans (Delcourt *et al.* 1993). The absence of human-induced fires and of big grazers leads to significant shifts in the structure and functions of those ecosystems, as has been demonstrated in the prairie ecosystems of United States (Pyne 1982). Another example is the present savannah ecosystem of Cuba, which has been shown to be a product of long-term human impact by combined cutting, burning and grazing (Borhidi 1988).

Even some desert ecosystems have been shaped by human-induced fires. Burrows and Christensen (1994) have concluded that the relatively high plant diversity in the Australian desert is due largely to the activities of aborigines who used fire extensively for many purposes (including increase of food resources) over vast tracts of the Australian desert for thousands of years. With the departure of aborigines to settlements in the 1960s and the resultant decrease in the frequency of fires, plant diversity (and probably mammal diversity also) has been substantially reduced (Figure 11.2-4).

Biswas (1994) has compiled information on land degradation in drylands of the world, concluding that some 30% of irrigated lands, 47% of rainfed croplands, 73% of rangelands and 69% of agriculturally-used drylands have been degraded (Table 11.2-11). However, little information is available on the relationship between degradation of drylands, habitat loss and loss of biodiversity.

Some of the most diverse, dynamic and complex wetland ecosystems are comprised of natural rivers and their riparian zones. Given the dependence of most forms of life on water, river systems and their riparian zones are especially important in the regulation and maintenance of biodiversity, playing a fundamental role in the movement of organisms and other nutrients. These habitats have significant ecological interactions with the sea, the atmosphere, and the terrestrial surroundings of the river

Table 11.2-11: Global status of land degradation in drylands of the world (Biswas 1994).

Figure 11.2-4: Numbers of plant species within a 100-metre radius plot with time since last fire in desert vegetation near Lake Mackay, Western Australia (from Burrows and Christensen 1990).

(Naiman 1992). Riverine systems have been profoundly influenced by damming, channelization, and other engineering works that reduce their diversity and dynamism. As of 1988, some 39 000 large dams had been constructed, creating reservoirs larger in total than the area of California or France (International Commission on Large Dams 1988); more than 100 dams with heights greater than 150 metres have been constructed, creating reservoirs that cover 600 000 km² (an area greater than the North Sea) and have a capacity of 6000 km³ equivalent to 15% of the annual runoff of the world’s rivers (Pierce 1992). The reservoirs created by dams therefore represent substantial new aquatic habitats, though these tend to be occupied by common and widespread species. The new

reservoirs also tend to replace much more diverse habitats, including waterfalls, rapids and floodplain wetlands, leading to the loss of the numerous species of plants and animals specific to running waters (Dynesius and Nilsson 1994). As a result of habitat destruction and obstruction to the dispersal of fish and other organisms, many riverine species may have been extirpated over large areas and others have become fragmented and therefore more prone to future extinction.

While dam construction is the most obvious human intervention leading to the loss of wetland habitats, other engineering works also cause problems. For example, straightening rivers decreases the retention of matter and energy, and naturally functioning floodplains provide wildlife habitat and help reduce or buffer non-point-source pollution (Petts 1984).

Wetlands – including estuaries, mangroves, open coasts, floodplains, freshwaters (streams and rivers), lakes, peatlands, and swamps – have been lost due to a wide range of factors (Table 11.2-12).

The industrialized countries have had an especially profound impact on rivers. Dynesius and Nilsson (1994) found that 77% of the total water discharge of the 139 largest river systems in North America north of Mexico, Europe and the Republics of the former Soviet Union is strongly or moderately affected by fragmentation of the river channels by dams and by water regulation resulting from reservoir operation, inter-basin diversion and irrigation. Rivers are also being influenced through human activities in their catchments, which are being influenced by embankments, draining, deforestation, urbanization and industry (Turner *et al.* 1990). The remaining free-flowing large river systems are relatively small and nearly all situated in the far north, as are the 59 medium-sized river systems of Scandinavia. Modifications to riverine systems

Key: ○ = Absent or exceptional; + = Present, but not a major cause of loss;
 ● = Common and important cause of wetland degradation and loss.

include three major effects on biodiversity: the habitats for organisms adapted to natural discharge and seasonal water-level regimes are impoverished; the role of each river as a corridor is reduced; and the riparian zone is no longer able to serve effectively as a filter between upland and aquatic systems (Dynesius and Nilsson 1994). The available data indicate that many types of riverine ecosystem have been lost and that the populations of many riverine species have become highly fragmented, possibly with profound implications on biodiversity.

While it is well known that riverine faunas have been reduced due to the factors outlined above, it is too early to tell whether the faunas have reached a new equilibrium or whether additional losses are to be expected. The time needed for re-equilibration of ecosystems is undoubtedly longer than the relatively few decades over which rivers have been significantly regulated by dams and diversions (Dynesius and Nilsson 1994).

Many other wetland habitats have also been lost, judging from the available data. The USA has lost at least 54% of

its original wetlands, while losses in European countries range from 60% to 90% (Dugan 1990). In developing countries, especially in Asia, ricefields have replaced many of the natural wetlands – the loss may amount to as much as 1.3 million km² (Tolba *et al.* 1992). While coastal wetlands have not been lost at such a high rate, many mangroves have been replaced by shrimp ponds; while global figures are not available, the Philippines have lost over two-thirds of their mangroves and Thailand has lost 40% (Tolba *et al.* 1992).

Coral reefs are another highly diverse wetland ecosystem type that has been profoundly influenced by human activity. While reliable global data are scarce due to lack of field research, Wilkinson (1993) has reviewed data from many parts of the world to conclude that coral reefs of the world are declining so rapidly that localized extinctions are probable. The major threats to reefs come from anthropogenic pollution, sedimentation and over-exploitation, all of which are increasing with increasing human economic activity. While coral reefs are highly

resilient and are unlikely to be adversely affected by climate change (Wilkinson and Buddemeier 1994), they are vulnerable to chronic stress from sources such as pollution. While data are sparse, Wilkinson (1993) concludes that 10% of the coral reefs of the world have already been degraded beyond recognition; 30% are in a critical state such that they will be lost or severely damaged within the next 10 to 20 years; another 30% will be grossly damaged in 20 to 40 years; and about 30% appear likely to remain healthy into the far distant future. The status of coral reefs is clearly responsive to human management action (Phongsuwan and Chansang 1993; Lidell and Ohlhorst 1993).

More generally, a decline in biodiversity has been associated with specific land-use changes associated with economic development, such as power line construction (Nickerson *et al.* 1989), urbanization (Leidy and Fiedler 1985), colonization adjacent to protected areas (Neumann and Machlis 1989), and forest fragmentation (Harris 1984; Hanson *et al.* 1990). However, economic development in urban and peri-urban habitats does not invariably mean loss of all of the original biodiversity and, in addition, new habitats such as urban parks, urban forests, urban wetlands, domestic gardens, roadside plantings, etc. may result in increases in both population densities (in certain species) and local biodiversity (Tables 11.2-13 and 11.2-14). Urban

Table 11.2-13: *Impact of urbanization on biodiversity: dependence of bird biomass and diversity on urbanization in Finland (Nvorteva 1971; Goudie 1993).*

	City (Helsinki)	Near rural houses	Uninhabited forest
Biomass (kg/km ²)	213	30	22

Ulu Gombak Forest Reserve	Extraction track in logged forest	400
Ulu Gombak	Virgin jungle reserve	400

biodiversity is discussed in greater detail in 11.2.3.3 and Section 13.3.8.1.

In conclusion, habitat loss clearly has been a major proximate cause of the loss of biodiversity, though surprisingly little accurate information on habitat loss is available globally. Changes in the distribution and quality of most habitat types are difficult to determine, even with the availability of satellite imagery. The problem is especially difficult in developing countries due to problems such as inadequate ground-truthing, less comprehensive satellite coverage, and the difficulties in identifying and classifying regional habitat types (Sisk *et al.* 1994).

11.2.2.4 *Indirect negative effects of species introduced by humans*

11.2.2.4.1 *Introduction.* As early as 1958 Elton recognized the effect of invasive species as ‘one of the great historical convulsions in the world’s fauna and flora’. The history of invasions is of course older than the history of humankind, some mixing of species certainly occurring without human intervention, but this section is concerned only with human-induced invasions of species. Historical aspects of invasions were dealt with in Chapter 11.1.

Species are introduced into alien habitats by people for a number of reasons. Levin (1989) identified three major categories: (1) accidental introductions; (2) species imported for a limited purpose which then escape, and (3) deliberate introductions. Many of the introductions relate to the human interest in providing species that are especially helpful to people. This is particularly true of agricultural species; indeed, in most parts of the world, the great bulk of human dietary needs are met by species that have been introduced from elsewhere (Hoyt 1992). Species introductions in this sense, therefore, are an essential part of human welfare in virtually all parts of the world. Further, maintaining the health of these introduced species of undoubted benefit to humans may require the introduction of additional species for use in biological control programmes which import natural enemies of, for example, agricultural pests (Waage 1991).

As a biodiversity issue it is not always possible to identify invasions as inherently ‘bad’; di Castri (1989) asserts that overall, the central European flora has undergone an enrichment of diversity over historical time as a result of human-induced plant invasions. Britain’s mammalian fauna totalling about 49 species includes some 21 introduced species, including eight large mammals (wild goat *Capra hircus*, fallow deer *Dama dama*, Sika deer *Cervus nippon*, Indian muntjak *Muntiacus muntjak*, Chinese muntjak *Muntiacus reevesi*, Chinese water deer *Hydropetes inermis*, Bennett’s wallaby *Macropus rufogriseus bennetti*, reindeer *Rangifer tarandus*). It is thus highly likely that, due to human influence, the mammalian fauna of Britain is more species-rich now than at any time

Table 11.2-15: Known numbers of invasive and native species in various countries/areas.

Country/area	Number of native species	Number of invasive species	Source
Australia (plants)	15 000–20 000	1500–2000	Groves 1986
New Zealand (plants)	1790	1570	Heywood 1989
Hawaii (plants)	956	861	Wagner <i>et al.</i> 1990
Tristan de Cunha (plants)	70	97	Moore 1983
Campbell Island (plants)	128	81	Moore 1983
South Georgia (plants)	26	54	Moore 1983
Southern Africa (freshwater fish)	176	52	De Moor and Bruton 1988; Bruton & Van As 1986
California (freshwater fish)	83	50	Moyle 1976

since the Neolithic. The genetic diversity of this fauna is very high, including species originating from Asia, North America, Europe and Australia (Jarvis 1979). Jacobs (1975 in Goudie 1993) provides the example of the transformation of the saline Lake Nakuru from an ecosystem of very low diversity (a large population of flamingoes, two species of algae and a few invertebrate species) to one of much higher diversity (including 30 species of fish-eating birds) after the introduction in 1961 of a fish, *Tilapia grahami*, to control mosquitoes.

Despite some positive effects on biodiversity at the local level, however, overwhelming evidence indicates negative effects on species and genetic diversity at both the local and global level. Such introductions can lead to severe disruption of ecological communities (Smith 1972; Zaret and Paine 1973; Mooney and Drake 1986; Drake 1989; Carlton and Geller 1993), and heavily influence the genetic diversity of indigenous organisms. Some protected areas established to conserve native species have been profoundly affected by introduced species (Bratton 1982) and on some islands introduced species closely match or even outnumber native ones (Table 11.2-15). Globally almost 20% of the vertebrates thought to be in danger of extinction are threatened in some way by invasive species (Table 11.2-16). The single biggest tragedy is the probable loss of at least 200 of the 300 endemic cichlid species in Lake Victoria as a result of the introduction of the Nile perch, *Lates niloticus* (Lowe-McConnell 1993). This was exacerbated by eutrophication of the lake and the introduction of new fishing gear. The global effects of certain invasive species such as the European pig, *Sus scrofa* (Oliver 1994), rats, *Rattus* spp. (Atkinson 1985; Stuart and Collar 1988; Brockie *et al.* 1989) and two aquatic plants, *Salvinia molesta* and *Eichhornia crassipes* (Ashton and Mitchell 1989) also attest to their widespread effects.

11.2.2.4.2 *Introduced species and their distribution.* Although the absolute number of invasive species is an unknown (Heywood 1989; Carlton 1989) an order of

magnitude estimate is possible. From the range of data on invasive species in Table 11.2-16 it is clear that many thousands of species are involved (and from a much wider range of organisms than is shown here). However, they still constitute a relatively small proportion of total species diversity (Macdonald 1992).

Invasives have been found in almost every part of the world (with the possible exception of Antarctica (Macdonald *et al.* 1989 quoting Usher pers. comm.). At least some invasive species have been found in a wide range of nature reserves surveyed by Macdonald *et al.* (1989), covering eight of the 14 terrestrial biomes identified by Udvardy (1975). Lake and river systems have also been seriously affected (Zaret and Paine 1973; Barel *et al.* 1985; Miller *et al.* 1989; Roberts 1990; Holcik 1991; Allan and Flecker 1993; Lowe-McConnell 1993) and, although less well documented, it is clear that invasives seriously affect nearshore marine environments particularly through accidental introductions in ships' ballast (Carlton 1989; Chew 1990; Carlton and Geller 1993).

It would seem that not all ecosystems are equally affected. Mixed island systems have higher absolute and proportional numbers of invasives than any of the continental biomes; within continental biomes xeric environments (including warm deserts and semi-deserts, tropical dry forests and woodlands) tend to have fewer invasive species; among temperate regions, reserves in the Southern Hemisphere have often experienced severe invasions while those in the Northern Hemisphere seem relatively free of invasions (Loope *et al.* 1988; Usher *et al.* 1988; Macdonald *et al.* 1989).

11.2.2.4.3 *Effects of invasive species and ecosystem susceptibility.* Much time and effort has been expended in investigating susceptibility of ecosystems to invasions and various factors have been implicated. A key factor in the literature is human-induced disturbance of ecosystems (Elton 1958; Arthington and Mitchell 1986; Brooke *et al.* 1986; Myers 1986; Ashton and Miller 1989; Carlton 1989;

Table 11.2-16: The percentage of threatened terrestrial vertebrate species affected by introductions in the continental landmasses of the different biogeographic realms and on the world’s islands. The total number of threatened species in the realm is given in brackets.

	Percentage of threatened species affected by introductions								
	Eurasia	North America	Africa	Indo-Malaya	Oceania	Australia	South America	All mainland areas	All mainland areas
	% (n)	% (n)	% (n)	% (n)	% (n)	% (n)	% (n)	% (n)	% (n)

Ramakrishnan and Vitousek 1989; Neiring 1990); but successful invasions of undisturbed ecosystems are also common (Macdonald and Richardson 1986; Ashton and Mitchell 1989; Kruger *et al.* 1989). Ecosystems of low diversity may also be susceptible (Brockie *et al.* 1989; Rejmanek 1989) as well as those without predators, herbivores or competitors (Atkinson 1985; Macdonald and Frame 1988; Loope and Mueller-Dombois 1989; Mack 1989; Macdonald *et al.* 1989). Climatic and edaphic similarity between the invader’s new and home environment may also be important (Holdgate 1986; Myers 1986; Diamond and Veitch 1989).

Invasive species are known to have wide-ranging effects on ecosystems, affecting both ecosystem structure and function. They may eliminate native species directly through animal predation or the browsing effects of herbivores as has happened, for example, in fish (Balin *et al.* 1985), molluscs (Wells 1995), and many bird species (Atkinson 1985; Brockie *et al.* 1988).

It is important to note that the many references to global extinctions due to invasives refer to islands or aquatic ecosystems and Macdonald *et al.* (1989) state that there has been no known global extinction of a terrestrial, continental species as a result of an invasive species. However, many examples of local eliminations or species brought to the brink of extinction by invasives can be quoted, including:

- the massive changes in species composition of temperate grasslands in Australia, South America and western North America as a result of the introduction of ungulates which have destroyed native plant communities (Mack 1989);

- the devastating effect of introduced trees and shrubs on the *fynbos* and *karoo* plant formations of South Africa which threaten over 50% of the 1808 plant species known to be under threat and which have caused substantial reduction in the local diversity of native fauna (Breytenbach 1986; Macdonald *et al.* 1989);
 - the elimination of the American chestnut *Castanea dentata* as a dominant tree over much of the eastern USA as result of the introduction of the plant fungal pathogen *Cryphonectria* (= *Endothia*) *parasitica* (Elton 1958; von Broembsen 1989), and
 - the elimination of the Atlantic salmon *Salmo salar* in more than 30 rivers in Norway as a result of the introduction of the conspecific Baltic salmon for aquaculture purposes. The latter carried the monoengean fluke *Gyrodactylus salaris* which proved to be deadly to the Atlantic salmon (Johnsen and Jensen 1986; Heggberget *et al.* 1993).
- Invasive species may also act in concert to threaten native species in a variety of direct and indirect ways. In Australia early European settlement caused severe fragmentation of habitat through the widespread clearance of vegetation (e.g. in the development of Western Australia’s wheat-belt) and this alone was responsible for a significant loss in native fauna. However, European settlement also brought with it the rabbit (*Oryctolagus cuniculatus*) and the fox (*Vulpes vulpes*). Rabbits soon reached plague numbers and led to further habitat destruction and failure of regeneration in remnant vegetation. Foxes were also able to reach high numbers

preying on the rabbit population and as a result had a considerable impact on other prey items – native mammals, reptiles, frogs, scorpions and large insect species. Once rabbits reached plague proportions, programmes to poison, fumigate and destroy burrows were introduced, killing rabbits but also inadvertently killing the native bilbies (*Macrotis lagotis*) and bush-tailed possums (*Trichosurus vulpecula*). The introduction of myxomatosis in the 1950s successfully reduced rabbit numbers but forced foxes to turn more to the remaining native species for food. Thus the introduction of these two species and later attempts to control them had a variety of effects on native species (Hobbs and Saunders 1994).

Certain species have been shown to have a range of indirect effects which can have an impact on several species and sometimes whole ecosystems. Invading aquatic macrophytes such as *Salvinia molesta* and *Eichhornia crassipes* (arguably the world's worst aquatic weeds) can spread prolifically by virtue of their rapid growth and relatively high biomass. While they may displace native plant species, they may also impede water flow, inhibit the penetration of light, increase evapotranspiration and alter water chemistry to such an extent that the water body no longer supports a functioning aquatic community (Humphries *et al.* 1994).

Other examples of indirect effects include the probable extinction of the snail *Bulimulus darwini* on the Galapagos Islands as a result of the destruction of its habitat through the effects of introduced goats (Coppo 1995); the reduction in the bird community around Lake Atitlan as a result of the introduction of the predatory fish species *Cichla ocellaris* which dramatically altered the trophic structure of the lake (Zaret and Paine 1973); and the prevention of recruitment of holly and oak trees in Ireland through the shading and impenetrable litter layer produced by the introduced *Rhododendron ponticum* (Usher *et al.* 1986).

Another serious effect at the ecosystem structure level is the genetic effect on species through hybridization or serious losses in genetic diversity. Invasive hybridization with local species has been recorded in ducks, wild cats, donkeys, fish, birds and grasses (Moyle 1976; Brooke *et al.* 1986; Macdonald *et al.* 1989; Holcik 1991; Ryman 1991; Hammer *et al.* 1993).

The consequences of invasions on ecosystem function are generally less well studied than those on ecosystem structure (Ramakrishnan and Vitousek 1989). This is an equally vital area since such changes can alter the conditions of life for all of the organisms in an ecosystem, often to the detriment of many native species. Effects of invasive species on ecosystems can alter soil erosion rates and other geomorphological processes (affecting such ecosystems as sand dunes, rivers, estuaries etc.), biogeochemical cycles, hydrological cycles, nutrient cycles

and fire regimes (Macdonald and Jarmen 1984; Macdonald *et al.* 1989). In summary, virtually all of the myriad ecosystem functions have been affected by introduced species (Macdonald *et al.* 1989).

11.2.2.4.4 Recovery of invaded ecosystems. Clearly, where endemic species have been exterminated, as has happened on islands and in aquatic systems, the effect of invasions is irreversible. However, in most cases invasives reduce local diversity or abundance of a given population, or alter community structure, and removal of these invasives is often accompanied by recovery of the biota (Veitch 1985; Brockie *et al.* 1989; Loope *et al.* 1989). However, this can be a very slow process. For example, rabbits and hares were introduced to the atoll of Laysan in the Hawaii group in 1903 as a source of meat for a cannery and within 20 years the number of plant species had fallen from 25 to four. After the extermination of the rabbits and hares, recovery proved to be much slower than destruction: seven years after the extermination of rabbits and hares there were nine plant species and after 38 years the number had risen to 16 (Goudie 1993). North *et al.* (1994) have shown rapid recovery of some native plant and animal species after elimination of non-native goats and rabbits but conclude that since many of the components of the original vegetation have been lost and other non-native species added, the developing ecosystem will inevitably differ from the original. Many invasive species have proved impossible to eradicate (Barel *et al.* 1985; Ashton and Mitchell 1989) or at least extremely difficult and costly to eradicate once well established (Macdonald and Frame, 1988; Macdonald *et al.* 1989). Thus stringent measures to avoid unwanted species in introductions would appear to be justified on both ecological and economic grounds.

An interesting management dilemma arises when existing species respond to the introduced species in certain ways. For example, native giant kangaroo rats (*Dipodomys ingens*) in California continually modify their burrow precincts by digging tunnels, clipping plants and other activities, with this chronic disturbance to soil and vegetation promoting the establishment of introduced early successional plant species such as *Erodium cicutarium*, *Bromus madritensis* and other Mediterranean annuals. Schiffman (1994) found that species richness, cover and frequency of the introduced plants were significantly greater on kangaroo rat precincts; the introduced species had significantly larger seeds than the native species, apparently making them more attractive to the kangaroo rats. This mutualistic relationship, whereby both kangaroo rats and introduced species benefit, presents an intractable management dilemma, possibly making it impossible to restore valley grasslands where endangered giant kangaroo rats occur to conditions where native species dominate.

The general global picture is, then, one of tremendous mixing of species with unpredictable long-term results.

While many introduced species have special cultivation requirements which restrict their spread, many other species are finding appropriate conditions in their new homes while many more may invade their new homes and constantly extend their distribution, thereby representing a potential threat to local species. The future is certain to bring considerable additional ecological shuffling which will have both winners and losers, although the overall effect will probably be a global loss of biodiversity at species and genetic levels.

11.2.2.5 Pollution of soil, water and atmosphere

Pollutants stress ecosystems and may reduce or eliminate populations of sensitive species (Carson 1962). Contamination may reverberate along the food chain: barn owl populations in the United Kingdom have fallen by 10% since new rodenticides were introduced, and illegal pesticides used to control crayfish along the boundaries of Spain's Coto Doñana National Park in 1985 killed 30 000 birds (MacKenzie 1986). Soil microbes have also suffered from pollution as industry sheds heavy metals and irrigated agriculture brings on salinization. Acid rain has made thousands of Scandinavian and North American lakes and pools virtually lifeless, and, in combination with other kinds of air pollution, has damaged forests throughout Europe (Blank 1985; Schindler 1988; Bucher and Bucher-Wallin 1989). Marine pollution, particularly from non-point sources, has defiled the Mediterranean and many estuaries and coastal seas throughout the world, leading to impacts on the reproduction of some marine species (Delong *et al.* 1973).

The air is polluted mainly from the combustion of fossil fuels in power plants, industry, cars, houses, ships, etc. The main pollutants are carbon dioxide (CO₂), sulphur dioxide (SO₂), nitrogen oxides (NO_x), ammonia (NH₃), ozone (O₃), heavy metals and organic micropollutants. The concentration of CO₂ in the atmosphere is increasing annually by about 2.9×10^9 tonnes (Mooney *et al.* 1987), and may cause a warming of the Earth through the so-called 'greenhouse effect'. The impact of increased CO₂ in the atmosphere is not always negative, as some plants may gain considerable benefits from such increases; but it is apparent that increases in carbon dioxide have systemic effects on plant-insect herbivore interactions (Fajer *et al.* 1989; Freedman 1989). The SO₂, NO_x and O₃ released into the atmosphere may directly affect crops and vegetation including forests (Hutchinson and Meema 1987; Bucher and Bucher-Wallin 1989). SO₂ and NO_x oxidized and converted to strong acids are precipitated and affect terrestrial and aquatic ecosystems negatively, directly by decreasing pH and indirectly by mobilizing toxic metals, especially aluminium (Chia *et al.* 1984; Hildrew *et al.* 1984; Rosseland *et al.* 1990). Heavy metals and organic micropollutants are also toxic by-products decreasing air

quality. In heavily affected areas pollution is a threat to the health of animals, humans included, by the accumulation of toxics through the food chain (Peakall 1975; Porter *et al.* 1984; Reutergårdh 1988; Beryland 1991).

The deposition of airborne pollutants on grasslands can have significant deleterious effects. In southwest Poland, one of the most highly polluted regions in Europe, Breymeyer (1990) showed that the species composition of an area of grassland significantly affected by pollution was highly impoverished, with only three species of grasses making up 75–97% of the plant biomass. Above-ground growth of plants was severely stunted and the soil fauna was decreased in biomass and proportion of large fauna. Particularly noteworthy was the reduction in Oligochaeta which are important for decomposition. Above-ground insects were small and assimilated food less efficiently, consequently needing to consume more plant matter and providing less prey for birds and other predators.

Acid rain has numerous system effects (Eney and Petzold 1987). On poor, acidified soils in the Netherlands, Graveland *et al.* (1994) found that many passerine birds produced eggs with thin and porous shells, leading to high incidence of clutch desertion and empty nests. Eggshell defects were found to be caused by calcium deficiency which in turn is caused by acid deposition. Acidification has also been implicated in greatly increased mortality of moose (*Alces alces*) in Sweden by leading to trace element imbalance, specifically deficiencies in essential trace elements such as copper and chromium (Frank *et al.* 1994).

The employment of chemical fertilizer on a large scale is around 150 years old (Goudie 1993) but the escalation in its use for food production has been most dramatic in the second half of this century, with a rise in world fertilizer use from 14 million to 143 million tonnes between 1950 and 1989. North America and Europe are still the dominant users but the gap is closing as tropical countries, particularly in Asia, develop agricultural practices requiring heavy use of fertilizers (Lean *et al.* 1990). Fertilizers have played a vital role, for example, in India's Green Revolution (Kothari 1994a).

That fertilizers have played an essential part in producing the world's harvests is undisputed: Lean *et al.* (1990) estimate that if the use of fertilizers ceased, the world's agricultural harvests would be cut almost in half. However, the negative side of the equation is that the nitrates from fertilizers seep into groundwater aquifers (a 1984 survey in the USA showed that 8000 out of a sample of 124 000 wells had nitrate levels above that considered safe for human health; Lean *et al.* 1990) and they are seriously implicated in the eutrophication of lakes, rivers and coastal ecosystems, often causing drastic changes in the fauna and flora.

Long-range transported air pollutants are precipitated as dry deposits or as acid rain and snow with negative effects

on soil (chemistry and microflora), crops and forests (e.g. Hutchinson and Meema 1987; MacKenzie and El-Ashry 1989; Likens 1989). Pollutants from the mining industry, organic and inorganic wastes from private and industrial sources, and agricultural activities are deposited, and the negative effects on the biota can be considerable. Construction and use of roads spread dust, road material and heavy metals from gasoline combustion to nearby areas (Watkins 1991).

Organochlorine pesticides (DDT, aldrin, Dieldrin, lindane) were introduced globally in agriculture in the 1950s, at a time when polychlorinated biphenyls (PCBs) were being used increasingly in a wide range of industrial processes. The principal mode of transport may be the atmosphere (Richards *et al.* 1987; GESAMP 1990; Loganathan and Kannan 1994). Organochlorine pesticides are soluble in fatty tissues and are biologically persistent; thus they can accumulate in high concentrations and, as a result of the process of biomagnification, the top predators in an ecosystem tend to contain the highest concentrations. The toxic effects on these species can lead to genetic mutations, breeding problems, infant mortality, impaired immunological functions and even death (Carson 1962; Henny *et al.* 1980; Mason 1989, Loganathan and Kannan 1994; Swart *et al.* 1994). Pollution can have significant impacts on particular species. For example, European mink in northern Spain have over twice the level of PCBs that produce reproductive failure in American mink in captivity (López-Martín, *et al.* 1994); and high organo-chlorine residues are associated with premature births in California sealions (Delong *et al.* 1973), other reproductive problems in several species of seal (Helle *et al.* 1976; Reijnders 1986) and, most recently, with impaired immunological functions in harbour seals, *Phoca vitulina* (Swart *et al.* 1994). In India, high pesticide residues have been found in several threatened species, though it cannot be stated conclusively that this is the main cause of threat. A long-term study in the Bharatpur National Park in west India showed high levels of pesticide residues in the Sarus crane. Other preliminary studies point to the role of pesticides in the high mortality rates found among raptors such as the peregrine falcon and the osprey (Rahmani 1989; Osman 1991).

For these reasons such pesticides have been banned in industrialized countries. However, they have found an increasing and lucrative market in the developing world. For example, Mowbray (1986) documents the sale in the South Pacific of 589 pesticide compounds that are banned or restricted in their countries of origin or are regarded by WHO as highly hazardous.

Acid sulphur and nitrogen products precipitated from the air affect water quality and thereby aquatic vegetation and animals (Hynes 1960; Henriksen *et al.* 1992; Rosseland and Staurnes 1994). Heavy metals from anthropogenic sources such as industry waste-waters, land deposits and

mining activity are affecting the water quality and the biota. The acidified precipitation can also mobilize trace metals and enhance their bioavailability (Vesely, 1994). Eutrophication of aquatic systems due to runoff of fertilizers from agriculture, increased nitrogen runoff from acid precipitation, or of nutrients and organic matter from sewage may lead to blooms of toxic algae, oxygen deficits or even the production of the highly toxic hydrogen

Box 11.2-6: Human impact on lake habitats: characteristics of lakes experiencing 'cultural eutrophication' (Mannion 1992; Goudie 1993).

Biological factors

- (a) **Primary productivity:** usually much higher than in unpolluted water and is manifest as extensive algal blooms.
- (b) **Diversity of primary producers:** initially green algae increase, but blue-green algae rapidly become dominant and produce toxins. Similarly, macrophytes (e.g. reed maces) respond well initially but due to increased turbidity and anoxia (see below) they decline in diversity as eutrophication proceeds.
- (c) **Higher trophic level productivity:** overall decrease in response to factors given in this box.
- (d) **Higher trophic level diversity:** decreases due to factors given in this box. The species of macro- and micro-invertebrates that tolerate more extreme conditions increase in numbers. Fish are also adversely affected and populations are dominated by surface dwelling coarse fish such as pike and perch.

Chemical factors

- (a) **Oxygen content of bottom waters:** usually low due to algal blooms restricting oxygen exchange between the water and the atmosphere. Oxygen-deficient conditions (anoxia) develop, especially at night when algae are not photosynthesizing. Thus seasonal and diurnal patterns of oxygen availability change. The decay of algal blooms also produces anoxia.
- (b) **Salt content of water:** this can be very high and provides a further restriction on floral and faunal diversity.

sulphide in lake and marine sediments (Mannion 1992; Goudie 1993) (Box 11.2-6). Aquatic life is also threatened by organic, chlororganic and other micropollutants from polluted rain, pesticides from agriculture, drainage from dumps and fillings, industry outlets, airport drainage, etc. Marine environments are polluted by organic waste and chemicals (e.g. antibiotics) from fish farms and inorganic (e.g. from antifouling paint) and organic waste products from ships, runoff and land-based discharges and airborne pollution from distant sources (e.g. Atlas and Giam 1981; Anon. 1989; Muir *et al.* 1992), etc. Table 11.2-17 summarizes the relative contribution of all potential pollutants from human activities which enter the sea as estimated by GESAMP (1990).

Chemicals added to ecosystems by human action can have profound ecosystemic effects. Peterson *et al.* (1985), for example, report that a river in northern Canada was transformed from a heterotrophic condition to an autotrophic condition through the addition of phosphorus from air pollution. Higher nutrient input from agricultural runoff (and also from human wastes) increases the primary production of coastal waters (80–90% of nutrient input is taken up by primary production in estuarine and nearshore waters; GESAMP 1990) and has, for example, increased primary productivity in the Baltic Sea by 30% (Hammer *et al.* 1993). However, this has not been followed by an increase in decomposition and the net result has been the production of anoxic conditions in deeper waters, either impoverishing or completely eliminating benthic communities. These conditions have also substantially reduced the spawning area for cod – which require, for successful spawning, a minimum salinity only found in the deeper waters of the Baltic. But there have also been other repercussions of high nutrient runoff: the higher turbidity resulting from runoff has caused a reduction in the *Fucus* community in deeper waters and an increase in filamentous algae which have taken over their role. The balance of species within the Baltic community has changed, with fishes such as bream and roach increasing at the expense of

Table 11.2-17: *Relative contribution of all potential pollutants from human activities which enter the sea (GESAMP 1990).*

Source	Contribution %
Offshore production	1

Runoff and land-based discharges	44
Atmosphere	33

whitefish, pike and perch (Hammer *et al.* 1993). The effects have therefore been far-ranging, affecting both biodiversity and the integrity of the ecosystem.

11.2.2.6 *Global climate change*

In coming decades, a massive ‘side-effect’ of air pollution – global warming – could play havoc with the world’s living organisms (Peters and Lovejoy 1992). Human-caused increases in ‘greenhouse gases’ in the atmosphere are likely to commit the planet to a global temperature rise of 1–3°C during the next century, with an associated rise in sea level of 1–2 metres. Each 1°C rise in temperature will displace the limits of tolerance of land species some 125 km towards the poles, or 150 m vertically on mountains. Satellite altimeters are becoming sufficiently sophisticated to measure changes in sea level, indicating rates of sea level rise of 3.9 ± 0.8 mm per year, substantially more than had earlier been estimated (Nerem 1995). Many species will not be able to redistribute themselves fast enough to keep up with the projected changes, and considerable alterations in ecosystem structure and function are likely. In the United States rising seas in the next century may cover the entire habitat of at least 80 species already at risk of extinction. Many of the world’s islands would be completely submerged by the more extreme projections of sea level rise – wiping out their fauna and flora, not to mention human habitations. And protected areas themselves will be placed under stress as environmental conditions deteriorate within them and suitable habitats for their species cannot be found in the disturbed land surrounding them. As the effects of climate change will be felt most profoundly in the future, this topic is covered more fully in Chapter 11.4.

11.2.3 *Forces driving human impact on biodiversity*

The root causes of the loss of biodiversity are not in the forest or on the savannah, but are embedded in the way societies use resources. They lie in human social organization, burgeoning human numbers, the way in which the human species has progressively broadened its ecological niche and appropriated ever more of the Earth’s biological productivity, the excessive and unsustainable consumption of natural resources, a continuing reduction in the number of traded products from agriculture and fisheries, economic systems that fail to set a proper value on the environment, inappropriate social structures, and weaknesses in legal and institutional systems (WRI, IUCN and UNEP 1992). These are discussed in more detail below.

11.2.3.1 *The rules governing the use of biological resources*

11.2.3.1.1 *Introduction.* The way human beings view, use and maintain elements of biodiversity is greatly dependent

on the way human society is organized. The changes in social organization among humans as new technologies were developed also provided new and powerful means by which people influenced biodiversity, in both positive and negative ways. This sub-chapter discusses a range of the key issues involved, considering the impacts of various attitudes towards nature, and the impacts of various kinds of human interrelations, including economic, cultural, political and intellectual factors.

11.2.3.1.2 The impact of cultural values on biodiversity. The diversity of human societies is reflected in the diversity of perceptions people have of their environment. Any classification of such cultural values will necessarily mask some of this diversity. However, some contrasting attitudes and examples to illustrate these attitudes are given in Box 11.2-7.

These attitudes overlap, and are not exhaustive. Nor do the set of attitudes on the left, or those on the right, necessarily go together in any one society; for instance, the modern animal rights movement may consider all creatures as equal, and yet think of nature as wild and humans as civilized (Marquardt 1993). Moreover, these attitudes are ideal types, and will not necessarily be found in their pure forms in any society. Rather, societies both over time and over space can be placed on a continuum between these opposites, as human attitudes change due to internal social dynamics and external influences. However, it is clear that such attitudes greatly influence how humans use natural resources, and therefore the impacts they have on biodiversity. Individual actions are often (though not always) based on what a person thinks of as ‘right’ and ‘wrong’, ‘good’ and ‘bad’, terms which are defined by the dominant ethical paradigm of the society the individual is living in.

For most of human existence, societies arguably have been characterized more by the set of attitudes on the left, and even now many tribal societies live by an ethical paradigm in which nature is valued both in its own right

Box 11.2-8: Wilderness is a state of mind.

One of the most powerful images of modern urban industrial societies is of ‘wild’ or ‘virgin’ nature. Anthropologists and others have shown that this is very different from the way indigenous communities have looked at nature (Gómez-Pompa and Kaus 1992). In Colombia, the forests of the northwest Amazon basin harbour a diverse array of plants and animals. This region is often considered part of the world’s greatest remaining tropical wilderness. But for the Tukano people who live there, it is not a wilderness, it is home, and they perceive their ‘wilderness’ environment to be anthropogenic, transformed and structured in the past by the symbolic meaning their ancestors gave to resources and the knowledge they obtained about the plants and animals that enabled people to survive. Their forest is a system of resources in which the energy produced is directly proportional to the amount of energy it receives. They know that they cannot harvest more than the forest can produce, and they apply sophisticated knowledge of individual species and their uses. Their myths tell of animal species that were punished by the spirits for indulging in gluttony, boastfulness, improvidence and aggressiveness. These myths serve as object lessons to human society, in which animals are metaphors for survival. By analysing animal behaviour, the Tukano find an order in the physical world within which human activities can be adjusted (Reichel-Dolmatoff 1976).

and for its role in spiritually and materially nurturing humans (recent compilations on this point include India International Centre Quarterly 1992; Suzuki and Knudtson 1992; Hamilton 1993; Kemf 1993; Carmichael *et al.* 1994) (Box 11.2-8).

Box 11.2-7: Contrasting attitudes about nature.

Humans as one strand in nature’s web	vs	Humans set separate from nature
All living creatures considered equal	vs	Humans superior to all creation
Culture/nature as a continuum (no such thing as wilderness)	vs	Culture/civilization human, and nature considered wild
Natural way is right, and human activities should be moulded along nature’s rhythms	vs	Human technology is superior, needs to mould nature to suit human needs
Nature has an integral set of different values (cultural, spiritual, material)	vs	Nature is predominantly a material (economic) resource

Traditional societies have often ‘set aside’ parts of the natural landscape they live in, or left untouched some of its elements. Most such societies, for instance, have considered certain sites as sacred (Chaitanya 1992; Gadgil and Chandran 1992; Carmichael *et al.* 1994), where most or all human activities are prohibited. Most societies have also considered certain species as sacred, with elaborate myths and folk tales about how humans originated from such species, or how these species are incarnations of, or in some way associated with, gods and deities, or how they have magical powers. These could be wild species which are undisturbed (and therefore have survived in even the most densely populated and radically altered human landscapes, such as rhesus and bonnet macaques in Indian cities), or domesticated plants and animals whose utilitarian value is intertwined with spiritual values (such as the cow in Hinduism). Such belief systems can have the effect (although perhaps unintentional) of regulating resource use.

Some traditional communities have formed resource regulation systems. For example, many traditional communities – whether ‘indigenous’ or ‘tribal’ like the Tara’n Dayaks of West Kalimantan (Padoch 1993) or non-tribal, such as the ribereños of Amazonian Peru (Pinedo-Vásquez *et al.* 1990; Pinedo-Vásquez and Padoch 1993) – establish community reserves and formulate rules about how the species therein can be exploited, with the express intention of preserving these resources for the existing community and for future generations. Therefore, in some cases reserves may be protected by religious sanctions and in others by a more overtly ‘social’ contract, and enforced by strong economic and social sanctions. Combinations of approaches are also found.

Indeed, utilization, respect, enjoyment and other values have usually been integrated into an inseparable whole in

traditional societies. In one village of the Mebengokre, an Amerindian group in Brazilian Amazonia, Posey (1990) found over 60 species of birds, turtles, lizards, snakes, amphibians’ and mammals being raised. Nurturing the ‘pets’ provides a valuable education by teaching children the behaviour patterns and feeding habitats of different animal species, and serves to reinforce cultural and social links between the people and their environment. Most were eventually eaten.

Notions of sustainability of use are inherent in the value systems of many traditional societies, usually manifested in some notion of inter-generational equity. The Iroquois tribe would plan for the seventh generation when making their decisions – the life-span, incidentally, of the dominant tree in their region (Suzuki and Knudtson 1992). The Koyukon Indians believe that future events will depend on the way people behave today and that the world can be nurtured by prudent use or harmed by unrestrained abuse. But equally important, the natural world will respond to gestures of respect given by those who recognize its sensitivity and awareness, and humble themselves to its power (Nelson 1989) (Box 11.2-9).

While it is indisputable that many indigenous populations appear to be well adapted to their environments, and even enhance biodiversity, most cultures maintain beliefs or practices that unnecessarily imperil their well-being (Edgerton 1992). Some of these customs and beliefs are indeed unacceptable in modern civilization, such as slavery (Mitchell 1984), infanticide (Neel 1970; Hausfarter and Hardy 1984), human sacrifice (Harner 1977; Davies 1981; Stein 1988), homicide (Chagnon 1988), feuding (Hallpike 1977; Chagnon 1988; Ferguson 1989), suicide (Rubenstein 1987), forced migration (Anthony 1990), and environmental pollution (Rambo 1985; Chagnon 1988). Edgerton (1992) argues that some beliefs concerning witchcraft (Lindenbaum 1972), the need for revenge (Keiser 1986; Chagnon 1988), and certain traditional practices involving nutrition (Cassidy 1980), health care, and the treatment of children (Miller 1981; Scheper-Hughes 1987; Goodman and Armelagos 1988) have been harmful as well. In short, while some traditional societies have had a relatively harmonious relationship with nature (Marshall 1959; Herskovits 1972; Bennett 1976; Ellen 1982), life in such societies has not been free from human discontent and suffering (Campbell 1975; Dirks 1980), and some have been unable to cope with the demands of their environments (Turnbull 1972; McGovern *et al.* 1988; Yoffee and Cowgill 1988; Tainter 1988). A generalization that can be drawn from this is that people are not always wise, and the societies and cultures they create are not ideal adaptive mechanisms, perfectly designed to provide for human needs (Turke 1990). A more balanced view is that traditional beliefs and practices may serve as important adaptive mechanisms, but they may also be inefficient, harmful and even deadly.

Box 11.2-9: Respect for nature in Alaska.

Many indigenous people exhibit behaviour that underlines their respect for the prey that supports their way of life. The Koyukon Indians of Alaska, for example, have an elaborate code of respectful behaviour that governs their relationship toward animal species. Red squirrel meat should not be cooked on a stick; women must never mention the brown bear’s name, beaver bones should be returned to the water; hunters must avoid bragging about prowess. These and numerous other very specific rules govern their way of life. The Koyukon limit their own harvests, guided by a thorough knowledge of population levels and ecological relationships, and restrained by their traditional code of ethics (Nelson 1989).

Clearly, some societies adapt to changing conditions better than others (Davis 1977; Laughlin and Brady 1978; F  rer-Haimendorf 1982; Eder 1987). Kuran (1988) has criticized the several theories seeking to account for such variability, which generally ascribe lack of adaptation to personal conservatism or collective conservatism – both forms of attachment to past choices. The key factor in successful adaptation appears to be the presence of feedback mechanisms which allow consequences of decisions to influence the next set of decisions, which enable societies to adapt to changing conditions.

When local people are part of a local ecosystem, their behaviour directly affects their own survival. But cultural mechanisms that have been developed as adaptations to the environment over tens or hundreds of generations are quickly cast aside when trade or new technology frees people from traditional ecological constraints, changing them from what Dasmann (1975) calls ‘ecosystem people’ who are adapted to their local ecosystem, into ‘biosphere people’ who can draw from the resources of the entire world.

While changes in traditional attitudes towards nature can be a result of internal dynamics (e.g. population increase), it is perhaps more often a result of outside influences: interaction with a modern culture, intrusion of the market, and so on. Redford (1990) has argued that in South America, at least, traditional resource use patterns may be sustainable only under conditions of low population density, abundant land, simple technology and limited involvement with a market economy, so that when confronted with market pressures, higher population densities, new technologies, and increased opportunities, few indigenous peoples can maintain the integrity of their traditional methods. This argument also applies to traditional fisheries management systems in the insular Pacific (Johannes 1978). In tropical Asia, on the other hand, some traditional systems have supported high populations and intensive agriculture for centuries. However, at least some such groups have fought hard to maintain their identity, and are seeking expanded international support for their efforts.

One of the lessons from recent work in ethnobiology and traditional ecological knowledge is that some indigenous views of conservation may differ from conventional biological views but nevertheless are legitimate in their own right (Berkes 1987; Alcorn 1993; Gadgil *et al.* 1993). One of the main differences between these two sets of views is that traditional concepts of conservation tend to be user-orientated; there have been no documented cases of a ‘traditional preservation ethic’. Yet many indigenous groups have practices that help maintain ecological processes and the species that mediate these processes (Alcorn 1989). Thus, the area of common interest between Western conservation scientists and indigenous wise-use

conservationists is biological sustainability. A major paradigm change among some Western conservationists is that some kinds of human use are accepted as part of conservation planning, as done in the updated World Conservation Strategy (IUCN/UNEP/WWF 1991). According to this view, biodiversity cannot be conserved in the longrun without the support of indigenous and other rural peoples, and without attention to their views and needs (e.g. Gadgil *et al.* 1993). As Alcorn (1993) puts it, indigenous peoples’ goals match the broader goals espoused by many conservationists who recognize that most of the world’s biodiversity is found in landscapes already occupied by people.

The influence of modern attitudes towards nature is now global. Stressing the place of humans outside nature, and the need for and possibility of technology mastering nature, these attitudes tend to treat all biodiversity elements as material resources created for human use. Therefore, nothing is ‘wrong’ in the extinguishing of other life-forms if the pursuit of material well-being (called ‘progress’) is served by it. Also lost in much of modern thinking are notions of inter-generational equity, as the discount rates used by economists render long-term considerations non-viable (Daly and Cobb 1989). Such modern materialist views have directly or indirectly led to considerable over-exploitation of nature, and consequently to the loss of biodiversity (WRI, IUCN and UNEP 1992). However, it can be argued that the modern scientific world view is also essential in using resources sustainably, since this provides a better capacity to understand natural processes and products, and to use them rationally. Rolston (1993) believes that spirituality and science need not be at odds. The biological sciences describe what is the case in nature and enable us better to appreciate and conserve it. Ecologists, for example, often solve problems with numerous variables and make predictions based on those solutions (The Crucible Group 1994). Perhaps science does this better than folklore, mythology and religious beliefs. Science observes ecological reality in the world, and does not choose or assign this reality (though of course scientific tradition affects the way scientists perceive reality; Sprugl 1991). People may choose to conserve natural things because they are useful, but also because they marvel at the intricacy, diversity, complexity, beauty, order, natural history and creativity present in nature. Ethics is informed by the facts about nature, and these facts influence value judgements.

In a way, the human world-view of nature is coming full circle in parts of the modern conservation movement. Respect for nature, inter-generational equity, and other such values which characterized many traditional societies are again gaining ground, not just in the deep ecology (Wilson 1984) and animal rights groups (Regan 1983; Singer 1991), but also in more mainstream efforts such as

the UN General Assembly's *World Charter for Nature* (1982), the WWF's Network in Conservation and Religion, the IUCN's Working Group on Ethics, Culture, and Conservation, the World Commission on Environment and Development's *Our Common Future* (WCED 1987), the document *Caring for the Earth: A Strategy for Sustainable Living* (IUCN, WWF, UNEP 1991), the *Earth Charter* adapted by the UN Conference on Environment and Development (1992), and the Australian CSIRO Conference on *Nature Conservation: The Role of Networks* (in press). This is further explored in Section 13.

There is in all this an increasing realization that cultural and biological diversity are intimately and inextricably linked. Attitudes toward nature and toward fellow human beings are part of a society's culture, and the enormous diversity of cultures around the world has arisen in response to diverse biological, historical and physical environments, and has in turn influenced the management of these environments. As cultural homogenization sweeps across the world in the wake of modernization and westernization, the vast range of human knowledge, skills, beliefs and responses to biodiversity is also washed away, leading to great impoverishment in the fund of human intellectual resources. Loss of cultural diversity leads to loss of biological diversity by diminishing the variety of approaches to human, plant and animal coexistence that have been successful in the past, and by reducing the possibility of imaginative new approaches being developed in the future (Burger 1990; Mayberry-Lewis 1992; Suzuki and Knudtson 1992).

11.2.3.1.3 Property rights and the use of biological resources. Human societies display an enormous range not only of moral and other attitudes, but also of organizational forms, interpersonal and inter-community relations, and political and economic systems. Each of these systems tends to have a somewhat different impact on the way humans relate to and use resources, and therefore on biodiversity. While no comprehensive comparative work on such impacts is available, the following provides examples indicative of the complexity of the situation.

The object of the property relationship is often a biological resource: land, trees, wildlife, crops and so on. The property relationship may then be based around obtaining, guaranteeing, or controlling access to the resource, essentially securing the rights to deriving value from it by either use or exchange. Property rights are not absolute and unchanging, but rather a complex, dynamic and shifting relationship between two or more parties, over space and time. Numerous property regimes have been distinguished, including open (unregulated) access, communal (regulated) property, private property (including corporate property), and state property (Berkes and Farvar 1989). How each of these relates to the conservation and use of biodiversity and the impacts of changing from one to another regime, appears to be highly variable (Berkes 1989).

In considering the property regimes that affect access to resources in most parts of the world, the complications are many. For instance, more than one set of laws or legal systems may be in operation at any one time and place, affecting the same common property resource. The dynamics of land use and transformation at a particular site are significantly influenced by competition between different sources of legitimate authority, such as 'customary' or 'traditional' law and 'formal' legal systems (Moore 1986; Fortman 1990; Peluso 1992). Further complicating the matter, conflicting perceptions and negotiations over the meaning of land and other natural resources may affect the form of property relations (Dove 1986; Posey 1989). In addition, scholars have pointed to the importance of an individual's social position, derived in part from participation in various types of social networks, as central to an appreciation of the ways in which property relationships are formed and operate in any particular place (Berry 1989, 1991).

Painter (1988), for example, found that the crucial issue underlying the loss of biodiversity in Latin America was the gross inequity in access to resources. In eastern Bolivia, smallholders are locked in an intense struggle for development resources (such as access to markets, agricultural credit, transport facilities and similar services) with large-scale commercial agriculture enterprises, lumber companies and other interests. This competition appears as an inter-ethnic conflict between people who are native to the area and migrants from Bolivia's highland and Andean valley regions.

Following up on this point, Lele (1991) has made a convincing argument that differential access to resources and the resulting affluence for some, in the form of over-consumption, may be linked much more directly to environmental degradation than is poverty *per se*, in either the North or the South. It is much easier for an economically powerful country to gain access to the resources of less powerful countries by creating an economically powerful market demand. This can then encourage the countries who are hoping to tap into this market to harvest their resources at unsustainable rates, while the richer country can protect its resources for a later day. Although it does not necessarily make environmental sense to do so, many tropical countries have taken an economically defensible position of harvesting their forest as quickly as possible, thereby cashing in on the stumpage value of the standing timber and investing the capital in opportunities that earn a higher rate of return, at least in the short term. This tendency explains the boom-and-bust logging cycles that have characterized many small tropical countries. Timber concession policies are partly to blame, because they fail to combine forest tenure with capture of stumpage value, thus preventing either the government or concessionaires from detecting and responding to rising

stumpage values by improving logging practices and reducing negative impacts on biodiversity (Vincent 1992).

Given this complexity, it is difficult to reach a general conclusion that any one of the forms of property regimes is necessarily, and in all circumstances, more conducive to conservation than another. The famous narrative of the 'tragedy of the commons', which, following Hardin (1968), presumed that conservation goals are best accomplished through either private or coercive state ownership, and that common property regimes led to over-exploitation, has been very widely criticised as emphasizing competition rather than cooperation and assuming the supremacy of individualism over communal interests (Ciriacy-Wantrup and Bishop 1975; Cox 1985; Berkes and Farvar 1992). Ample evidence has now been accumulated to show that common-property regimes do not inevitably lead to tragedy (Dasgupta 1983; McCay and Acheson 1987; Ostrom 1990), underlining the great difference between open access systems and regulated common property regimes. Renewed interest in the subject has stimulated a flurry of intensive studies of the performance of diverse common property institutions (Berkes 1989; Feeny *et al.* 1990; 1993; Ostrom 1990; Bromley 1992; Schlager and Ostrom 1992). Berkes and Farvar (1989) conclude that traditional systems have been the means by which societies have managed their natural resources over millennia on a sustainable basis. It is only as a result of these systems that any resources remain today.

A series of examples will illustrate the complexity of the property-biodiversity relationship. In Niger, resource use was controlled by time-tested rural systems such as carefully negotiated allotment of agricultural lands, wood-cutting rights within the territorial boundaries of sedentary communities, and the controlled use of water points and seasonal grazing lands by pastoral groups (Otto and Elbow 1993). These traditional systems regulated intra- and inter-group use of resources, which were allocated sequentially between various user groups. Many, perhaps most, hunter-gatherer, shifting cultivation, and traditional agricultural societies have had a combination of family proprietary rights over small intensively managed (usually cultivated) plots and clan/village/tribal group rights over larger foraging/hunting/fishing areas (McNeely and Pitt 1985; Ruddle and Johannes 1985). Biologically rich areas of the Sahel are often managed by rural populations through common property tenure arrangements which determine rights of access and responsibilities of the community (Lawry 1991). For example, sacred forests are managed by highly respected animist religious leaders who enforce rules governing access to remnants of primary growth forests (Freudenberger 1993a). Other ecologically diverse resources are considered private property of the resource users themselves. Dense concentrations of gum arabic trees (*Acacia senegal*) in the Ferlo of northern

Senegal are considered by rural communities to be the property of individual gum collectors, who protect 'their' trees (Freudenberger 1993b). In cases where no rules (imposed either through cultural traditional or legal institutions) effectively govern the use of open-access resources, ecological degradation can be severe (Hardin 1968).

Controlled comparisons between private and common property regimes are rare. One simple study in Zimbabwe showed that while as many as 99 species of trees existed on village communal lands, adjoining private farms had only 40 (McGregor, pers. comm. 1992). Other evidence suggests that private ownership can frequently lead to simplification of grown vegetation into a few commercially favoured crops, and that making the land a commodity itself creates conditions for its transfer to less conservation-orientated owners (Hecht 1988). Absentee private landowners are notoriously unsuccessful in conserving biodiversity (McGovern *et al.* 1988).

Place and Hazell (1993) did not find that fully transferable property rights (frequently lauded as the essential characteristic of private property) were a significant factor in affecting the kinds of investment that farmers made in improving their land, their use of input factors, their access to credit, or the productivity of their land. Farmers holding secure but communal rights were just as apt as those who could sell their land without prior approval to make long-term investments in the quality of land and to achieve equivalent yields. However, without secure tenure, rural communities can *only* afford to consider their own short-term interests. Without the security of realizing sustainable revenues, or returns from their investments, they are compelled to exploit resources for maximum immediate gain, regardless of future consequences for themselves, the resource base, or biodiversity. In Tanzania, past government interference with customary land-use rights has made rural people reluctant to make long-term investments in tree planting (IDA 1992), because they have no incentive to invest time, energy and capital if there is no assurance of reaping the benefits.

Ownership of land and/or resources by the State has been one method of securing property rights and regulating resource use. Various countries have tried to do so by nationalizing different resources, especially forests, land, water and minerals. However, many of these nationalization efforts ignore or overlook the reactions of the local peoples to such actions. In many parts of the world, the national plans or resource management strategies are imposed over pre-existing structures, thereby greatly weakening traditional systems of resource management that have functioned for hundreds of years and have deep historical, cultural and social roots. Changes in these systems result in loss of social control

mechanisms, and consequently lead to profound changes in resource use – usually in the direction of over-exploitation (Blaikie 1985; Berkes 1989; Vincent 1992; Dove 1993).

Similarly, government ownership has a chequered record in conserving natural resources. In many instances government ownership of forests has led to a concession economy, in which badly designed concession regimes have led to massive deforestation. In some tropical countries, forests and coastal areas are in effect ‘open access common pool resources’, open to use by anyone (Orstrom 1990). This status usually occurs despite property rights claims by governments or individuals. Such claims are often simply unenforceable in remote areas or where significant political pressure allows squatters to use vacant land. Under such conditions and with high use pressure, such open access (rather than communal property) may indeed lead to what Hardin (1968) termed ‘the tragedy of the commons’ in which all users rush to claim their share, despite long-term damage to the resource. In most cases, such local property rights disputes occur around resources with tangible economic value, such as timber, fish, or land that could be cleared for agriculture. Other biological resources, however, are often damaged or destroyed as a side-effect of the exercise of these rights.

A change in agricultural and land management technologies is often accompanied by a change in property regimes as well as by changes in biodiversity. The spread of irrigation is often also accompanied by a change from common property to individually owned plots and a reduction of access and decision-making by poor farmers, nomads, and women over land (Witfogel 1957). In the arid regions of western India, the Indira Gandhi canal has disrupted nomadic routes, allowing outside settlers to take over, and causing loss of native biodiversity as pastures and scrublands are turned into irrigated agricultural fields (Mukhopadhyay and D’Souza 1994).

The intrusion of the market is also very frequently the cause of a change in resource control and conservation regimes. Instead of using resources for subsistence, the people may elect to feed market demands and receive the benefits in financial returns rather than sustenance (Ekins 1993). In the northeast Indian states of Nagaland and Arunachal, tribals own the vast majority of forests in a variety of communal or private property systems. Once well protected by these systems, the forests are now being sold at alarming rates to outside timber and plywood markets, a process aided by lack of alternative income-generating livelihoods (required to obtain goods from the market), changes in local leadership, and alienation of the new generation from their lands (Kothari 1994b).

Attempts by the state to assume responsibility for species-rich areas for conservation purposes have often resulted in conflicting situations which, ironically, threaten biodiversity. Some of the most ecologically diverse areas,

such as the inland estuaries of the Senegal River, have been turned into state reserves managed by forestry and wildlife departments. Rural populations have been systematically excluded from use of these resources, and hence often harbour bitter feelings towards the reserves, a situation that frequently leads to poaching and other forms of abuse (Burnett and Stilwell 1990; Brandon and Wells 1992; Bergeret 1993). Several National Parks and sanctuaries in India, home to tribal and non-tribal peasant populations whose only stable resources are the forests, are now witnessing deliberate habitat destruction, or incitement to destruction by wood-poachers, by local communities who have been denied these resources (Basappanavar 1993; Kothari 1994a).

At the same time, the 9800 protected areas that have been established by all governments today cover over 925 million hectares, and provide one of society’s strongest defences against over-exploitation of particularly important sites (McNeely *et al.* 1994). Many of these protected areas provide significant benefits to local people and earn broad popular support (Barzetti 1993; McNeely 1993). On balance it appears that government intervention in favour of conservation is well justified by the power of modern civilization to over-exploit: protected areas are thus a legitimate expression of national sovereignty and usually make a significant contribution to national welfare. When local communities are forced to pay the costs of providing such national benefits, governments are seeking ways of providing appropriate compensation for the opportunity costs involved (McNeely 1988). (See Section 13 for a further discussion.)

11.2.3.1.4 Impact of access to information intellectual resource rights. Among the newest forms of private property are regimes that relate to intellectual resources. The rapid development of intellectual property regimes (IPRs) (patents and plant breeder rights being the ones most directly relevant to biodiversity) in the past few decades has raised serious concern regarding the impact of this new form of property on the conservation and sustainable use of biological resources.

The rapidly advancing field of intellectual property rights has profound implications for the relationship between people and biodiversity. IPRs represent a privatization of ideas and innovations, mirroring the transition from common/public to private/corporate ownership and access which is seen in the case of physical/natural property. IPRs originated with industrial inventions but recent decades have seen their increasing extension to the living world, culminating in patent applications even for human genetic material.

As in the case of physical and biological property, access to information provides people and societies with a powerful means of influencing natural resource use and management. Indeed, in the modern world, information is

power. It would appear that recent advances in information technology and telecommunications (television, satellite dishes, computer networks and the 'information superhighway') are breaking the boundaries within which information is held. O'Neal (1993) goes so far as to assert that an explosion of knowledge has reached the masses, breaking 'the monopoly of the world's literate classes'. However, information remains an instrument of power, as can be seen in the continuing attempt to monopolize it in the form of intellectual property rights.

Access to information has both positive and negative implications for biodiversity. On one hand, information provides technology which can enhance public health standards, improve the quality of life, and otherwise assist in solving difficult problems. The more pertinent information that becomes available, the more able people are to make decisions based on the best available knowledge, with a reasonable idea of the consequences. However, in most countries, information about major development projects, political and policy decisions, and other activities which have a direct bearing on people's lives and on biodiversity, are not easily accessible to the general public. Development in such an atmosphere of secrecy is likely to be less successful in reaching those whom it targets, and in achieving an optimum use of the intellectual resources a society possesses. In India, destructive development projects have been stopped on the basis of information leaked to the public. Conversely, they have been forced ahead where such information has remained in closed files or been inadequately distributed.

Information also comes with the biases of dominant groups in society: it is orientated towards the literate against the non-literate, and towards a few widespread languages against the more localized languages. Even conservation literature, for instance, suffers from these biases: most information on biodiversity-related debates is in English. These biases mean that a considerable number of people are not being informed, and that the debate itself is losing out on essential and diverse inputs.

On the other hand, access to information does not come with control of it. Many countries are unable to protect themselves from the onslaught of information, nor are they really able to regulate how they are perceived by others. The mass media, particularly those of the industrialized world, predominantly portray high-consumption lifestyles, with little focus on sustainable use of resources (Opole 1993). Since such portrayals now reach most of the world's population, the media may be a major force in enticing people and countries to strive for consumption patterns far beyond their economic and natural resource means. Mass media are also inherently homogenizing, since they cannot possibly be flexible enough to cater to the enormous diversity of local cultural and biological systems. This influence itself may have a negative effect on biodiversity,

for example, in driving demand for a few new high-status foods in place of a diversity of traditional menu items (e.g. rice and wheat taking over coarse cereals and millets).

There is also, paradoxically, an information overload, at least among those who have access to the dominant channels of communication, including governments. The change in information availability on ecology and resource management in recent decades has had a considerable impact on decision-makers. Carew-Reid (1993), in summarizing the environmental strategies that countries have embarked on in the past two decades, documents a bewildering array of initiatives, not necessarily exclusive, prepared at national levels with the help of many different international organizations, resulting in a smorgasbord of strategies – for example NCSs (national conservation strategies), TFAPs (tropical forest action plans), NEAPs (national environment action plans), NEMPs (national environment management plans), Green Plans, and Biodiversity Action Plans. Printed literature too is expanding at a bewildering rate: there are now several dozen professional, and thousands of amateur, journals/newsletters on matters relating to biodiversity.

The special role of women in biodiversity-related issues is now widely recognized. Dankelman (1993) summarizes the role of women as managers of the environment, beginning with their role in traditional hunter-gatherer societies: credited with collecting four times as much food as men, they have developed a thorough knowledge of plant and animal life and ecological processes. In settled agricultural systems women have often played an especially important role in domesticating animals, inventing selective breeding, domesticating most of the currently important crop plants, inventing tools, and establishing the use of ash as a fertilizer, mulching, terracing, fallowing and crop rotation.

Van den Oever (1993) identifies women as the primary educators of the young, though of course father-son education has also been extremely important in most cultures. Children (particularly girls) have traditionally helped their mothers with the daily chores associated with subsistence farming, fuelwood gathering and freshwater collection. Traditional knowledge is passed on to them orally from their mothers. While the importance of the education of women to at least primary or early secondary level is seen as an important component in reducing fertility rates and controlling population growth, Opole (1993) suggests that the development of education has also contributed to the loss of indigenous knowledge through the separation of young girls from their mothers as they go to school. The media, too, have played their part in making women (and children) a special target group for consumer goods advertising (Dankelman 1993).

If the foregoing discussion about property relations and biodiversity is an indication, it would appear that the

possibility of conservation-orientated use of resources would be greater with decentralized political structures, everything else being equal. However, little literature is available to support this hypothesis. Nor is it possible to prove unequivocally, at the current state of knowledge, that democracies are better at conserving biodiversity than dictatorships: experience from Africa, for instance, suggests that either may be possible. However, given that democracies are more amenable to other aspects of social relations which may facilitate conservation (e.g. access to information, secure land tenure and resource rights, participation in decision-making, flexibility in dealing with diverse situations, etc.), such a relationship may be posited. Reed (1992) shows how the mismanagement of natural resources in Côte d'Ivoire, leading to severe deforestation, is a result of attempts by the ruling elite to maintain political power, and how this was made possible by a one-party system which repressed any challenge to official policies.

11.2.3.2 *Growth in human population and natural resource consumption*

The Earth's human population is increasing. Some 5.6 billion people currently occupy our planet and that number is projected to double within the next 60 years (UN 1992). More people means a greater need for agricultural and industrial produce, settlements, transportation, and infrastructure. More and more natural areas will be modified, though to what extent will depend partly on the number of people they support (Boserup 1965). This growth will have serious impacts on the levels of biodiversity that can be maintained.

In most countries with high fertility rates, about half the population is under the age of 16. The resulting demographic momentum – that is, high birth rates in coming years due to the large number of people who will be reaching their reproductive years – means that global population will continue to grow for at least the next half century and probably longer, barring catastrophe. Another billion people are likely to be added to the world population for each of the next three decades (UN 1992). The rates and magnitude of this growth and the eventual size at which the global population stabilizes – critical considerations for biodiversity – depend on social and economic measures, especially on the rate of economic development in the developing countries.

The problems associated with population growth and distribution and loss of biodiversity are reaching critical proportions in many parts of the world. In all but one of the seven mega-diversity countries which together contain over 54% of the world's flora and fauna – Brazil, Colombia, Mexico, Zaire, Madagascar, Indonesia and Australia – population growth exceeded the world's average for the period 1950–90. In these countries, population growth is expected to continue, and if present trends persist, population increases are likely to lead to higher

deforestation, degradation of land and loss of biodiversity. But the picture is seldom simple: Brazil, for example, has been experiencing an absolute decline in rural population since 1975 as rural people have moved to the cities. Declines in rural population can mean increased biodiversity in at least some cases where demand for biological resources also declines.

The impacts of population increase are felt in both terrestrial and aquatic habitats. Lundin and Linden (1993) estimate that already 66% of the Earth's population lives within 60 km of coasts and that population growth here is faster due to migration from inland areas. This has resulted in densities of 1000–2000 people per km² in the coastal zone of Asia, Central America and the Caribbean. Coastal migration affects developed and undeveloped countries alike: in recent decades migration to coastal areas of the Pacific Coast and the Gulf of Mexico has increased such that 50% of the US population now lives within 70 km of the sea (WRI 1994).

The average number of working-age people entering the labour force is about 35 million annually in developing countries, exacerbating the already serious problems of underemployment and unemployment. In the next 10 years, developing countries must generate 30 million new jobs each year just to absorb into the workforce the children already born. This means that the natural resource base of these countries will be increasingly under pressure if countries are unable to provide employment in industry and agriculture. For example, in India, almost 10 million entrants a year are projected in the coming decade. Since 73% of the Indian population is currently in rural areas, it is possible that agricultural lands and forests will need to absorb about 7 million new workers each year, placing additional pressures on already degraded resources (Bose 1991).

Population growth affects biodiversity: directly, through increased resource consumption; and indirectly, through fuelling the processes of poverty and migration, and causing a breakdown in social institutions determining the management of natural resources. However, the ways in which population pressure affects natural resources and habitats vary, and therefore it is necessary to understand the causes of such pressure before designing interventions for its control. One of the major causes is the effect of natural population growth on the regeneration rates of resources. Another cause is unsustainable resource consumption patterns, including excessive commercial use of resources, urbanization, and human uses of valuable or critical species. A third cause is increasing migration of poor people into ecologically fragile areas. Resource degradation can also occur when the population exceeds the social capacity of institutions to cope with environmental changes.

Human population density is clearly linked with wildlife habitat loss. The 20% of countries which have lost most

habitat in Africa and Asia (an average of 85% of habitat loss) had average population densities of 1888 persons per km². In the 20% which lost least habitat (an average of only 41%) population density averaged only 294 people per km². According to UNEP and Sadik (1992), 79–80% of deforestation results from population growth (though it is unclear whether the effects of changes in consumption patterns, discussed below, are included in this estimate).

As numbers have increased and new technologies have developed, humanity has appropriated an ever-increasing share of the Earth’s resources. People consume, divert or destroy an estimated 40% of the terrestrial productivity of photosynthetic plants, algae and bacteria (Vitousek *et al.* 1986), the fundamental source of the energy available for virtually all living systems. This trend appears to be unsustainable. The world’s biotic systems simply cannot accommodate an ever-growing claim on primary productivity to meet further growth in human population and consumption. The inherent limits of the natural resource base will impose a corresponding limit on the number of people who rely on it. Of course, an ecosystem’s (or, for that matter, a planet’s) ‘ecological carrying capacity’ can be increased by technology (as the history of agriculture demonstrates), but ultimate constraints on consumption are nevertheless real.

Ehrlich and Ehrlich (1990) give global population growth the primary importance in most environmental change because of the resources required to sustain the demands of over 5 billion people. They contend that population growth has exceeded the capacity of the biosphere to sustain it, under current levels of management. Simon and Kahn (1984) take an opposing position which holds that population increases stimulate technological and social advances that improve the conditions of life, so that greater numbers can transform the environment for the better (at least for humans).

Another view is that profit-seeking and capital accumulation require that natural resources be exploited at

an unsustainable level, wherein socioeconomic differentiation creates a situation in which the ‘haves’ place heavy demands on the world’s resources, driving environmental change, while the subsistence needs of the ‘have-nots’ put marginal environments under increasing stress (Blaikie 1985; Redclift 1987; Sweezy and Magdoff 1989).

Allen and Barnes (1985) and Rudel (1989) provide statistical evidence to support the idea that population growth drives or strongly contributes to forest clearance, at least in the tropics, while Anderson (1990) emphasizes such factors as uneven land distribution and a complex array of policies, institutions and economic forces that promote and reward forest clearing (Hecht and Cockburn 1989). Bilsborrow and Okoth-Ogendo (1992) conclude that population growth is an important factor in the destruction of tropical forests, but one that is significantly modified by the natural and institutional context within which the damage occurs.

Meyer and Turner (1992) suggest that population is an important global variable in that total world population is directly related to total biological demand for resources, but its connections to land-cover change become weaker at increasingly smaller spatial scales because of the importance of other variables that affect demand or spatially deflect its impacts. These other variables must be incorporated to improve our understanding of the human causes of the observed changes in land cover.

Consumption is an especially important variable, as more consumption inevitably means increased impact on resources (Boyden and Dovers 1992). The past few decades have seen the emergence of a powerful new drive in human society: consumerism (Durning 1992). Throughout history, some people in society have had the power and privilege to amass material wealth, and to consume considerably more than the average, but until recently they constituted a small minority (mostly rulers, upper status/class people, and the

Table 11.2-18: Some indicators of growth in global consumption of resources from 1950 to 1991 (Brown et al. 1992).

World indicator	1950	1991	Change (%)
Grain production (10 ⁶ tonnes)	631	1696	270
Soybean production(10 ⁶ tonnes)	18	106	590
Meat production (10 ⁶ tonnes)	46	173	380
Fish catch (10 ⁶ tonnes)	22	97	440
Irrigated area (10 ⁶ ha)	94	235	250
Fertilizer use (10 ⁶ tonnes)	14	136	970
Oil production (10 ⁶ barrels/day)	10.4	59	570
Natural gas production (10 ¹² cu. ft.)	6.7	77	1150
Automobile production (10 ⁶)	8	35	440

like). In contrast, in the industrial world today, and among the large middle classes of the developing world, consumerism is all-pervasive: indeed it defines what constitutes 'the good life' (Durning 1992). An indication of the magnitude of the growth in consumption can be gained by several indicators in the growth of global consumption of resources since 1950 (Brown *et al.* 1992) (Table 11.2-18). Particularly remarkable is the order of magnitude increases in fertilizer use and natural gas production.

Whittaker and Likens (1975) have estimated that an 'agricultural world' in which most human beings are peasants, should be able to support 5 to 7 billion people, probably more if the large agricultural population were supported by an industry-promoting agricultural activity. In contrast, a reasonable estimate for an industrialized world society at the present North American material standard of living would be one billion. At the more frugal European standard of living, 2–3 billion would be possible. These figures represent not just the contrasting material demands of developed and developing societies but also their contrasting dietary habits. Huxley (1984) considers that dietary habits lie at the root of many of our troubles and calculates that the average Westerner consumes 65 kg of grain per year while the meat consumed accounts for over 900 kg of grain per year. The average Chinese consumes 160 kg of grain and under 20 kg of meat per year. In short, the range of food required to feed 200 million in the West would feed 1500 million Chinese. However, the current change in the economic status of China and Southeast Asian countries will result in a shift towards Western levels of consumption with drastic implications for world food reserves and future demand, and resulting impacts on biodiversity.

Most Asian and African nations have predominantly rural populations (70.1% and 67.3%, respectively). In contrast, in developed countries and in Latin America about 75% of the population is urban. Over the past 40 years, there has been an unprecedented growth in the world's urban population and by the year 2000 it is estimated that nearly half of the world's population will be urban (WRI, 1994). Urbanization affects biodiversity in four main ways:

- Geographical expansion of settlements and infrastructure displaces the existing vegetation and diversity through land conversion.
- Urban activities indirectly have a significant impact on hydrological and atmospheric systems at both local and global levels.
- Urban dwellers plant many species of plants around homes, along avenues and in parks. These are largely ornamental and often introduced species which displace the native vegetation, while adding to overall diversity.

- Urban demands for biomass require fuelwood, industrial wood, sawnwood and other products such as fruits and flowers from surrounding areas. Around cities, plantations of genetically similar trees are displacing the local vegetation to meet the urban demands for biomass.

Urbanization and its effects on biodiversity are discussed in more detail below (11.2.3.3) and in Section 13.3.8.1.

Another way in which population change affects biodiversity is through population movements. Environmental degradation is both a cause and a consequence of frontierward migration. It is a *cause* when decreasing ecological capacity forces people to move elsewhere, often entailing clearing forests for settlements and agriculture. It becomes a *consequence* when increasing populations exert pressure on resources for livelihood; short decision-making time horizons prevent many poor farmers from investing in soil or forest conservation techniques, especially when payoffs are not immediate (Shaw 1989).

Resource extraction activities have motivated movement into frontier sites (Cruz *et al.* 1992), including those initiated or supported by governments and aid agencies. More than half the developing countries in the tropics with annual deforestation rates of over 90 000 ha have populations in excess of 55 million and average annual population growth rates of 2–5% since the mid-1970s. Close to 30 million people reside in forests and protected areas in India and Indonesia. In the Rondonia area in Brazil, the population of small-scale cultivators has increased by over 15% per year since 1975, a rate that is many times higher than Brazil's annual population growth rate. Similar mass movements into tropical forests and protected areas have occurred (WRI, UNEP and UNDP 1990).

While the magnitude of population pressures on the environment can be measured, and in some cases predicted, another dimension of population pressure which is relevant in the management of natural resources is the social and cultural characteristics of the population. These characteristics determine the capacity of groups in dealing with changes in resources and access rules.

Because of accessibility to markets and increased immigration, which are often linked to population pressures, very few frontier sites have culturally homogenous populations and even areas, and can show striking differences among groups in their population growth rates, migration patterns, and their land-use and resource consumption patterns. Three aspects of the composition of populations have especially important impacts on the management of biological resources: recognition of ethnicity; gender-specialized roles in conservation; and differences in socioeconomic status. In any particular habitat or ecosystem, the ways in which

resources are used and managed will differ among ethnic groups, between men and women, and between different socioeconomic groups. It is important to distinguish interventions in terms of which population sub-groups are most vulnerable to changes in resources (e.g. indigenous peoples, women, the poor).

11.2.3.3 Urbanization and biodiversity

The urban environment is a mosaic of human-made, natural and semi-natural habitats with climatic and hydrological conditions that distinguish it from adjacent rural areas (Berry 1990; McPherson 1994). While only 18% of cities are open space (Nicholson-Lord 1987), as much as 40–70% may be green and photosynthesizing (Nicholson-Lord 1987; Ignatieva 1994; Loucks 1994).

Around 45% of the world's population is urbanized but this is unevenly split between the developed countries (over 70%) and the developing countries (just under 40%) (Berry 1990; WRI 1994). However, the gap is closing and the urban growth rate in the latter is currently four times faster than in the developed countries and their urbanized area is predicted to double over the period 1980–2000 (UNEP 1992). Some general trends in city growth include:

- an increase in cities of over 1 million inhabitants (increasing from 190 in 1975 to over 400 by the year 2000; Berry, 1990);
- 'counterurbanization' in the developed countries with substantial numbers of people leaving core city areas for the less built-up suburbs (OECD 1985; Nicholson-Lord 1987; Berry 1990; Skibniewska 1994) leading to more disturbance of green-belt areas and more dispersed populations;
- higher numbers and growth rates of cities in coastal areas where 60% of the world's population currently lives (Walker 1990; Lundin and Linden 1993).

11.2.3.3.1 Effects of urbanisation on biodiversity. These can be considered from two perspectives: the direct effects urbanization has on biodiversity (the loss of habitat; the fragmentation of habitat; the creation of new human-made habitats such as cemeteries, derelict lands, rubbish tips, etc.); and the indirect effects it has through its impact on hydrological systems and the atmosphere. Another indirect effect which is considered elsewhere and will not be discussed further here is the effect on the rural environment of the urban demands for resources.

Indirect effects: Urbanization covers the urban landscape with impervious surfaces (one US study of an average, urban area estimated this at 12–37% of total urban area: Loucks 1994) and these have a dramatic effect on runoff, an effect which is exacerbated by extensive sewers and drain systems (Binford and Buchenau 1993; Goudie

1993). A comparison of contaminant profiles of urban runoff and raw domestic sewage indicates that urban runoff contributes more suspended solids, pesticides, chlorides and heavy metals while the sewage is the main source of nitrogen and phosphorus (Goudie 1993). The less soil available, the more concentrated are these chemicals when they arrive in the rivers.

Most African and Asian urban centres have no sewerage systems at all (UNEP 1992) and in developing countries human sewage is the most important pollutant of freshwater and coastal zones (Markham 1994). Sewage, both treated and untreated, contains high nitrate and phosphate loads and, together with the nutrients and contaminants from urban runoff, produces an assault on the aquatic environment that has resulted, at best, in eutrophication, and at worst, in its almost total destruction and associated loss of biodiversity.

Highly polluted systems are characterized by the loss of fish life and small, specialized benthic life (composed of chironomid larvae and tubificid worms) as was recorded for the River Thames in the 1950s (GESAMP 1990; Allan and Flecker 1993) and other rivers (Whiteley 1994). Eutrophication of rivers, nearshore marine ecosystems and semi-enclosed seas (such as the Baltic, Black Sea and Mediterranean which are naturally oligotrophic), although producing less profound effects on species diversity, alters species composition and destroys the integrity of the ecosystem (Caddy 1993; Hammer *et al.* 1993).

Urban centres have substantial daily freshwater needs. Abstraction can have serious effects on species diversity and composition, both within the river, where lower water levels affect the fauna and riparian vegetation (Binford and Buchenau 1993) and in the nearshore waters where rivers meet the sea. Reduced water flows have caused increased salinity in San Francisco Bay, the Caspian Sea, the Black Sea and the Mediterranean with effects including a reduction in fish populations and changes in the composition of fish communities (GESAMP 1990; Caddy 1993; Goudie 1993).

A common phenomenon near and within urban areas as a means of flood control, channelization drastically alters the physical characteristics of a stream, increasing water velocity and reducing habitat diversity and riparian vegetation (and thus nutrient input to the stream). As a result some species are eliminated and species composition is altered (Allan and Flecker 1993; Binford and Buchenau 1993; Goudie 1993).

City-produced contaminants (such as CO₂, SO₂, nitrous oxides, ozone, etc.) have effects within the city, close to the city and globally (Berry 1990; Hawksworth 1990; Westman 1990). Lichens have proved to be excellent monitors of sulphur dioxide pollution which has caused the absence of any species in the central areas of some major cities and their severe reduction in cover and diversity

(over 80% reduction in the worst cases) in polluted urban areas with potential knock-on effects on a range of vertebrates and invertebrates associated with them (Hawksworth 1990; Goudie 1993; Loucks 1994). Loucks (1994) suggests that such pollution effects, although not well documented, occur in other groups such as plants, birds and other biota. Urban air pollution also affects adjacent habitats: Westman (1990) records changes in the structure of the Californian coastal sage scrub ecosystem with replacement of native shrubs by exotic annual plants as a result of urban pollution, and Goudie (1993) reports on smog damage to Ponderosa pines 129 km away from the pollution source – Los Angeles. Finally, at the global level urban air pollution is implicated in the greenhouse effect, global warming and sea-level change, with all their associated effects on biodiversity (Berry 1990).

Direct effects: Obviously urbanization contributes to one of the key factors in loss of biodiversity – the loss of habitat – and since urban centres tend to be near rivers and coastal areas, wetlands and coastal ecosystems have been most affected (Walker 1990; Schmid 1994). For example, human settlement is seriously implicated in the current threats to important Asian wetlands (Scott and Poole 1989), in the loss of natural flood plains in North America and Europe (Allan and Flecker 1993), and the loss of much of California’s coastal sage scrub habitat (Westman 1990). However in terms of the extent of habitat lost the effects are not yet very serious. For example, the United Kingdom is highly urbanized and densely populated yet the built-up area of 1.3 Mha (Wynne *et al.* 1995) constitutes only 5.3% of total land area although it should be noted that urban development requires vast amounts of materials – rock, sand, gravel – which destroys natural habitat and alters the landscape (Douglas 1990). The densely-populated city-state of Singapore (45 869 people per km²), for example, still has considerable vegetation (see Box 11.2-10).

Perhaps a more serious effect of urbanization is that of habitat fragmentation and its effect on ecosystem structure and function. This has been the subject of much debate for over two decades (for a review of this issue, see Saunders *et al.* 1991). The process of fragmentation, as well as reducing the size of the habitat, causes changes in microclimate which affects the biota as do the size, shape and location of fragments in the landscape (Saunders *et al.* 1991). In addition, the biota themselves respond differently to fragmentation depending upon their size, life-history strategy and their role in important ecological interactions (predator–prey, pollinator–plant, etc.) (Cody 1986; Soulé and Simberloff 1986; Wilcove *et al.* 1986; Renman and Mortberg 1994). A useful general conclusion is that the smaller the remnant, the greater the chances of extinctions and disruptions of ecological processes altering species composition; and the greater the ‘edge’ effect which may alter species composition and may enhance invasion of alien species (Saunders *et al.* 1981; Wilcove *et al.* 1986). While the effects of fragmentation on natural and semi-natural urban areas is poorly documented, the above effects have been recorded in several cases (e.g. Renman and Mortberg 1994; Turner *et al.* 1994).

The search for solutions to the problem of habitat fragmentation has led to a whole new science of greenways or corridors – belts of land that link fragmented habitats (e.g. several papers in Smith and Helmund 1993; Hudson 1991). Although the benefits of such links in maintaining species diversity have been shown, negative effects are also possible, leaving the issue inconclusive at our present level of knowledge. (e.g. Simberloff and Cox 1987; Saunders *et al.* 1991; Noss, 1993).

Noss (1993) considers that roads are the single most destructive element in the habitat fragmentation process and that roads are also destructive in their own right, resulting in serious losses of wildlife through road deaths,

Box 11.2-10: Major vegetation types in Singapore.

Category	Type	Total area (ha)	Number of plant species	Number of species per ha
Primary	Rainforest	100	1200	200–300
Spontaneous secondary	Tall secondary forest	1600	400	80–110
Spontaneous secondary	Low secondary forest and scrub	4000	150	20–70
Spontaneous secondary	Herbaceous vegetation	6000	300	20–80
Primary and secondary	Mangrove forest	250	25	2–15
Managed secondary	Parks, gardens, etc.	2000	1000+	5–50

Source: Corlett (1992).

Box 11.2-11: Way (1977) records the following from an examination of roadside verges in Britain:

- (1) 870 species of mostly native plants (from a total of 2000 species), including 35 of the country's threatened species.
- (2) Breeding habitat for:
 - 20 of the country's 50 species of mammals
 - all 6 species of the country's reptiles
 - 40 of the country's 200 species of bird
 - 25 of the country's 60 butterfly species
 - 8 of the country's 17 bumblebee species
 - 5 of the country's 6 species of amphibian.

and aiding the transfer of non-native species and range extensions of native species (Noss 1991, 1993; Goudie 1993). However, the very specialized habitat of roadside vegetation reveals some surprising contributions to the conservation of native species (Box 11.2-11).

Some human-made habitats have lower biodiversity than their natural counterparts, (for example, the landscaped park versus forest (Corlett 1992; Hails 1992) although higher densities of certain species may be recorded (Goudie 1993; Gliwitz *et al.* 1994; Luniak 1994). But the urban environment includes a great diversity of habitats – refuse tips, sewage farms, waste ground, derelict ground, disused railway yards and railway rights-of-way, buildings (both inside and outside), pavements, parks, etc. – and the literature documents their value for wildlife (e.g. Wee and Corlett 1986; Goudie 1993; Ahern and Boughton 1994; Shepherd 1994; Trojan 1994; Whiteley 1994). In some cases these habitats play a significant role in the conservation of 'rare' species. For example:

- the rare limestone specialist plant which thrives well on the brick rubble of demolition sites and on limestone railway ballast in Britain (Shepherd 1994);
- the number of nationally scarce beetle species in Britain which were found among the 60 beetle species thriving on the shop floor of a factory six years after its closure (Whiteley 1994);
- the rare US prairie species found alongside railroads and highways where they are protected from agricultural activities which have destroyed much of the original prairie habitat (Ahern and Boughton 1994).

The modern planning ethic, beginning perhaps in the 1970s with the recognition of urban ecology as a separate discipline, is placing more emphasis on the maintenance of

biodiversity in the urban environment (Nicholson-Lord 1987; various papers in Platt *et al.* 1994 and Smith and Hellmund 1993). Thus urban areas should be seen as management challenges for those concerned with biodiversity, not simply as sterile biological wastelands of interest only to humans (see discussion in Section 13.3.8.1).

11.2.3.4 Consequences of increasing demand for resources

As technological advances in transportation and communication have made the world smaller, trade between all parts of the globe has increased in magnitude and frequency. Now a major force in the relations between and within nations as witnessed in the recent negotiations over the General Agreement on Trade and Tariffs (GATT), trade has profound impacts on biodiversity. While the impact on biodiversity of various kinds of trade (including a comparative assessment of barter and monetized trade), and the effect of trade liberalization, has not yet been evaluated systematically, some indicative trends can be discerned.

The global market tends to separate resource management from the consumers, so feedback systems which work at simpler levels of technology, and which require corrective action from people, are no longer operative. In fact, one major difference between local people and the global market system – between ecosystem people and biosphere people – is the differential opportunity for escape. That is, the market can easily move from one place to another for its resources, but the local people are stuck in situ (Dasmann 1988). The rules of democracy, with voters making decisions about the fundamental choices of society, apply within national boundaries; but in the global market, companies can often elude decisions they do not like and look across national boundaries to find lower wages or labour standards, more permissive environmental laws, or laxer financial regulations (Daly 1992; Dionne 1993). This can apply at the governmental as well as corporate level (Box 11.2-12).

An obvious conflict also exists between an international policy of free trade and a national policy of internalization of external environmental costs. A country that internalizes environmental costs into its prices will be at a disadvantage in free trade against countries that continue to externalize these costs (Daly 1992). A weakening of domestic environmental norms could result.

Another aspect of trade which becomes a factor in biodiversity loss is 'tariff escalation', the practice of levying progressively higher tariffs on more processed goods. This discourages commodity producers from adding value to their exports by processing them. Tropical products in particular are targets for tariff escalation practised by developed countries. Even after the Uruguay Round it is still applied to tropical timber, coffee, cocoa and various tropical fruits. In West African and Asian

Box 11.2-12: Trade in toxic waste.

The cross-border trade in toxic waste began as a general practice in the late 1970s and continued to grow throughout the 1980s and into the 1990s. Although just a handful of industrialized countries produce 95% of the world's hazardous waste, the international trade of that waste has been encouraged by global economic relationships. Extensive and increasingly inexpensive transport and communication networks, put in place for trade in commodities, has facilitated the trade in toxic wastes. This movement has been driven by cost factors spurred by environmental concerns in waste-producing countries. For example, while the disposal cost per tonne of hazardous waste in the USA in the 1980s was upwards of US\$250, in Africa waste was being dumped for as little as US\$2.50 per tonne.

By the late 1980s, 30–45 million tonnes of toxic waste made its way across borders every year. Over half of this trade appeared to be with non-OECD countries, with some 20% going to Third World countries.

The resulting damage to biodiversity and the environment more generally from the import and recycling of hazardous waste harms the economies of these developing countries. In many cases the waste contamination effects begin to show themselves over the long term in the diminished health of people, lower agricultural productivity of land, contamination of the food chain and of ground water, and harm to wildlife and biodiversity.

In brief, global trade links have enabled waste to be moved cheaply, and poverty and international debt patterns have encouraged its movement to less industrialized countries in need of foreign exchange. This process can only compromise economic development prospects in the future and thus fuel a vicious cycle of poverty and environmental damage. In several cases, waste traders have bypassed international regulations by relabelling hazardous wastes as commodities to be recycled.

In early 1994, the 'Third World-NGO Alliance' was successful in raising the issue of a ban on the Movement of Hazardous Waste and its Disposal. However if this ban is successful and stops the dumping and recycling of hazardous waste in poor countries, it may lead to an increase in transfers of dirty technology and the movement of entire dirty industries to non-OECD countries (Clapp 1994).

countries, at least, this necessitates the use of a larger amount of land for plantations than would be needed if exporting processed crops could earn them as much foreign exchange as they get exporting the raw materials.

Subsidies for the production of commodities or processed goods can encourage over-exploitation of natural resources and degradation/pollution of the environment. Examples include agricultural and energy subsidies in the industrial countries, especially in eastern Europe and North America. Conversely, when developing countries are forced to relinquish agricultural import controls, dumping of subsidized food increases, with attendant economic, social and environmental impacts. Small-scale farmers are forced to intensify production on fragile lands, and/or are displaced from their land when they are undercut in domestic markets by cheap, subsidized imports (Box 11.2-13).

In the case of other economic sectors (industry, fisheries, mining), the example of India is instructive. Since 1990, the country has begun 'opening up' its economy to free trade, and is consciously moving towards an 'export-driven economy'. Analysis of the economic activity consequent on this transformation suggests that severe social and ecological disruption is resulting (PIRG 1993, 1994). The exploitation of marine products, for instance, has increased; 56 fishing and fish processing projects, and 19 aquaculture projects, all of which are 100% export-orientated, were cleared in the period 1992–3 at a time when the fish catch was stagnant due to previous overfishing. Discontent among India's several million small-scale fisherfolk is running extremely high due to the large-trawler-orientated fisheries policies of the government (Kothari 1994b, 1995). Apart from its impact on local fisherfolk and coastal ecosystems in general, specific concern has also been expressed about the implications of trawler operations on endangered marine species of fauna. For instance, at least one and possibly four jetties are being constructed or planned close to Bhitarkanika Sanctuary, in the eastern Indian state of Orissa, to service deep-sea trawlers. Bhitarkanika harbours the world's largest nesting colony of the Olive Ridley turtle, a severely endangered marine reptile. Several other protected areas in India are threatened with denotification by state governments eager to open them up for commercial exploitation (Kothari 1995).

Another facet of trade which threatens biodiversity is the often highly lucrative trade in wild species. Although such trade has led to significant declines of populations and endangerment of some species in the past (e.g. the long history of trade in crocodile skins; Thorbjarnarson 1992), today it is characterized by its elevation to global status for a much larger number of species which are sought after by more affluent populations. The range of species involved and the size of the trade are quite staggering. It is estimated that annually this involves (WWF 1994):

Box 11.2-13: Trade, maize and biodiversity in Mexico.

While it is admittedly difficult to generalize about the effect of trade agreements on biodiversity world-wide, the probable effects of the North American Free Trade Agreement (NAFTA) on the great diversity of maize in Mexico may be an indicator. Mexico is within the primary region of maize diversity: the crop occupies around 35% of the arable land, with 72% of all farms producing it (Salcedo, *et al.* 1993). Most maize producers are small peasant farmers (Montañez and Warman 1985; CEPAL 1982). Though the last 40 years have seen dramatic changes in Mexican agriculture, with the adoption of modern cultivation methods and laboratory-generated seeds, farmers continue to plant landraces (Hibon *et al.* 1992). Government support has been essential for the maintenance of many small farmers producing maize. However, the Mexican government is now changing the economic and institutional environment of peasant agriculture, including modifications to the Agrarian Law, eliminating price supports and subsidies to inputs and marketing infrastructure, and opening the borders to foreign imports of crops such as maize, particularly under NAFTA (Hewitt de Alcantara 1991; Salcedo *et al.* 1993; Solleiro *et al.* 1993). Many farmers, particularly small peasant producers, might not be able to compete in this changing environment (Levy and Wijnbergen 1991; Salcedo *et al.* 1993), especially because the price of American maize is substantially lower than Mexican maize (at least partly due to hidden subsidies to the US maize growers). As a result they may stop planting maize altogether, at least in many agro-ecological niches currently used for the crop. This may translate into a significant loss of the maize diversity that has contributed to maize production in this country and world-wide (Mangelsdorf 1974; Goodman and Brown 1988). Other impacts on biodiversity could occur if large-scale, chemical-intensive monocultures replace the small-scale farms, and if the displaced farmers turn to alternative forms of livelihood that are environmentally harmful.

- 26 000 live primates
- 2 million live orchid and cactus plants
- 1 million live birds
- 45 000 wild cats
- 10 million reptile skins
- 9 million reptiles

However, the trade presents a dilemma. Trade places a market value on wild species, encouraging sustainable exploitation rates and indeed the trade in most wild species is sustainable and a valuable source of income for local people. Yet the very global status of today's trade coupled with the rising affluence of potential buyers has brought certain naturally rare or already endangered species to the brink of extinction through over-exploitation. Such is the value of trade in wildlife that controls on trade at both national and international levels (the latter through the Convention in International Trade in Endangered Species of Wild Flora and Fauna (CITES)), as they have become tighter and more effective, have encouraged the development of a highly sophisticated illegal network with low investment costs and potentially huge profits. For example, the uncovering of an illegal crocodile-skin trading operation by CITES revealed that the skins, obtained in South America and shipped to Europe and Asia, produced profits of more than US\$60 million, and a macaw (which can only be traded illegally) can be bought in a South American market for US\$100 and sold for US\$5000–6000 in European and North American markets (Le Duc, 1990).

Appendix I of CITES (which prohibits all trade in a species) lists over 600 threatened species of animals and plants that are, or might be, affected by trade (Burgess 1994). The scale of the trade and its very nature in some instances where the 'rareness' of a species adds dramatically to its value, constitutes a growing threat to an increasing number of species. Jenkins and Oldfield (1992) attest to the appeal to collectors of the rare and the unusual in the plant world and cite the examples of the Mexican cactus, the south Indian lady's slipper orchid and the giant pitcher plant as species that have been driven near to extinction by collectors. This kind of valuation of wildlife clearly puts some of those vulnerable species (those that are rare or of limited distribution) in high demand.

The illegal trade in rhino horn (used for medicinal and ornamental purposes) has been almost entirely responsible for the drastic decline of black rhinoceros over most of its range in Africa during the last 15 years (Cumming *et al.* 1990), and the exploitation of tiger parts for the Asian medicinal market is currently the biggest threat to the survival of the tiger already under severe pressure from habitat loss (Jackson and Kempf 1994). Mills and Servheen (1991) describe the trade in bears and bear parts (particularly gall bladder) in Asia where the rising affluence of some Asian countries is increasing the demand to the extent that trade in four species of Asian bear is a threat equal to or greater than habitat destruction and human encroachment. In South Korea these authors record that bear gall bladders are priced, gram per gram, at up to 18 times the price of gold. Similarly, when one considers that the sale of one tiger skeleton can yield profits worth more than ten times a year's salary in some countries

(Table 11.2-19), a continuing illegal trade, even when populations are critically low, seems almost inevitable.

11.2.3.5 *Economic systems and policies that fail to value the environment and its resources*

Many conversions of natural systems (such as forests or wetlands to farmlands and rangelands) are economically and biologically inefficient. They happen partly because of the urgent need for agricultural land, regardless of how sustainable cultivation is, and partly because natural habitats are commonly undervalued economically (Hufschmidt *et al.* 1983; Orians *et al.* 1990; Swanson and Barbier 1992; Pearce and Moran 1994).

Further, with the levels of uncertainty and the inability of scientists to predict future events, can anyone be sure that all the benefits and costs have been accurately accounted for? How much of a risk can society take in depleting the genetic resources that exist today, based upon current levels of knowledge? Even for countries that might appear to be able to afford further reduction of natural capital stocks, the risks from so doing are still high because of: (a) imperfect understanding of the life-support functions of natural environments (de Groot 1992); (b) the fact that losses are often irreversible; and (c) lack of substitutes for those functions, even if their loss is reversible in theory. Some economists therefore posit a rationale in terms of uncertainty and irreversibility for conserving the existing stock, at least until society has a clear understanding of what the optimal stock is and how it might be identified (Pearce *et al.* 1990).

Biological resources are mis-valued for several reasons. First, many biological resources are consumed directly and never enter markets. Among forest products, sawn timber, pulpwood, rattan and gums are likely to be marketed while much of the food, fuelwood, and medicinal plants harvested by local people will be consumed directly by them or their families (Collier 1990). Accordingly, the economic values of unsustainable logging and other

potentially exhaustive uses are overestimated while sustainable uses (and aesthetic and spiritual benefits) are underestimated, creating incentives to impoverish biodiversity (Desaigues and Point 1993).

Second, biodiversity’s benefits are in large part ‘public goods’ that no single owner can claim (Ciriacy-Wantrup and Bishop 1975; Berck 1979; Stevenson 1991). Wetland protection, for example, benefits the public tangibly and quantifiably, but the benefits are so diffuse that market incentives for wetland conservation seldom develop. This undervaluation then justifies government policies (such as tax incentives) that further encourage wetland conversion to uses with greater ‘market value’.

Third, property rights are more likely to be granted to those who clear and settle forests and other lands covered with natural vegetation than to forest dwellers living by the sustainable harvest of natural products (Dasgupta, 1983; Repetto, 1988; Price, 1989). Formal property rights are also often easier to obtain by people living in cities and working in the formal sector of the economy – which itself favours the extraction and marketing of products such as timber over the sustainable harvest of products with limited market value. Any uncertainty over property rights weakens incentives for stewardship and encourages over-exploitation. Few farmers will plant woodlots that they might not own five years later. People who do not benefit from a tourist industry, but need food, are more likely to kill than to protect wild animals. People who have no stake in a resource are the least likely to care for it and the most likely to alter it if doing so establishes ownership (Stevenson, 1991).

Biologically diverse natural systems are major economic assets (Pearce and Moran 1994). But because such systems are commonly undervalued, biodiversity conservation is seen as a cost rather than an investment, a burden rather than an opportunity.

Business accounting is relatively routine. By comparing the balance sheet of a company from one year to another an

Table 11.2-19: Prices paid for tiger bone to poachers and middlemen in range states.

Country	US\$/kg	US\$ per skeleton	Per capita (average) GNP
Cambodia	100	1700	200
China	31–126	527–2142	435
India	15–200	255–3400	310
Lao PDR	12–76	204–1292	230
Nepal	100–130	1700–2210	180
Russia	20–300	340–5100	2100
Vietnam	100–375	1700–6375	220

Source: Mills and Jackson 1994.

owner can see whether a company is growing or shrinking, and how fast. Environmental accounting (sometimes called 'green accounting') seeks to provide similar measuring tools for the environment (Daly and Cobb 1989; Pearce *et al.* 1989; Howarth 1990; Costanza 1991; Craig and Glasser 1993). However, environmental accounting is vastly more complex than accounting in the business world. Not only is there no accepted methodology to perform environmental accounting, but consensus, at least over the near-term, is unlikely.

Business accounting deals with goods and services that can usefully be inter-compared in terms of their monetary value. It also generally operates over relatively short time-spans. Environmental accounts are far more complex. They must include the value of a landscape, of a species of bird or fish, and of an undammed river. They must not only reflect the direct cultural, spiritual, economic and social values of these entities to humans, but also the more intangible values of these entities as members of tightly coupled ecosystems. Environmental accounts must address change at many scales: local, regional and global. They must provide information about both the near-term and the distant future. Environmental accounting for sustainability must be able to incorporate and illuminate our ideas about what kind of a world we want to leave to the future (Norgaard 1992).

All accounting systems incorporate social values and perceptions about how the world is organized and how it will unfold. The way an accounting system is constructed – what it includes, what it excludes – affects both the kinds of questions it can answer and the kinds of questions it cannot answer. In environmental accounting, basic conceptual issues are a more fundamental matter. Different people are likely to value a river valley in very different ways: as a place to hike, swim, or watch a rare bird; as a dam site; as a resort site; as a place to raise and harvest a cash crop of timber; as the home and source of physical and spiritual sustenance for indigenous people; or as a speculative investment. An additional complication is that each individual may recognize a variety of senses of value.

The further to the future one seeks to plan, the more uncertain and unforeseen effects matter. For example, if a resource is unknown, or if it is known but considered to have no value, then it will not be represented in an accounting system. The idea is best understood from an historical example. In 1850, in the early stages of the Industrial Revolution, coal was the dominant energy mineral. An energy accounting system of 1850 would ignore oil, except possibly for a minor entry for whale oil used for lamps. There would be no mention of uranium, which in 1850 before the discovery of radioactivity and fission, had no conceivable utility. The 1850 accounting system would reflect knowledge and technology of the time. It would view coal as a source of heat energy, but

would miss its potential as a fuel for electricity generation. The valuation of known coal deposits would entirely miss the collapse in the value of coal following the discovery of massive oilfields later in the century.

No discussion of economics and biodiversity can be meaningful without some idea of what we think should be sustained and for how long. Sustainability is necessarily a normative notion that demands some relatively objective measures to indicate whether conditions are improving or deteriorating. Environmental accounting can rarely give precise answers, but it can be an enormous help in framing issues and in sharpening ideas. Daly (1990) provides a useful starting point, pointing out the two obvious principles of sustainably using renewable resources. First, that harvest rates should be equal or be lower than regeneration rates (sustainable yield). Second, that waste emission rates should be equal to or lower than the natural assimilative capacities of the ecosystems into which they are emitted. Regenerative and assimilative capacities must be treated as natural capital, and failure to maintain these capacities must be treated as capital consumption, and therefore not sustainable.

The two 'common sense' principles for the establishment of sustainable policies differ from traditional approaches to economic accounting in several ways. They are based on biological, geological and physical knowledge. They are directly coupled to observable systems with specific indicators of achievement. They are explicitly dynamic, and take account of rates: e.g. harvest rates, regeneration rates, waste emission rates, and the natural assimilative capacities of ecosystems. Daly's notions are consistent with the idea that natural capital can be consumed and transformed into other forms. For example, it may be more 'sustainable' to use a depletable resource rather than harvesting some resource indefinitely. Fossil oil, for example, might provide a springboard to sustainable photovoltaic electrical systems, thereby avoiding the damming of wild rivers.

Human inventions can change the character of resources, but they can never fully substitute for them. Daly (1990) clarified why natural capital and human-made capital are complementary, and why both are needed. Extra sawmills cannot substitute for diminishing forests; more refineries cannot substitute for depleted oilwells; larger nets cannot substitute for declining fish populations. On the contrary, the productivity of sawmills, refineries, and fishing nets (human-made capital) will decline with the decline in forests, oil deposits, and fish. Natural capital as a provider of raw material and energy complements human-made capital, just as natural capital as absorber of waste products is complementary to the human-made capital which generate those wastes.

The fact that environmental accounting incorporates perspectives on how the future will unfold is a major

strength as well as a problem. Accounting systems can help us expand the scope of our thinking. They can help us better understand points of view that differ from our own, thereby improving our ability to address previously unforeseen, but not unforeseeable, consequences of our actions. Accordingly, environmental accounting systems should also be able to capture the views of both technological optimists and technological pessimists; of those with little interest in 'natural' systems as well as those who believe that 'development' and 'quality of life' involve far more than an ever-increasing GNP.

Environmental accounting systems should attempt to represent the full set of goods and services provided by the global ecosystem. They should incorporate a multiplicity of notions of sustainability. They should incorporate distributional and intergenerational equity considerations, recognizing the concerns of those hurt by change (e.g. those displaced by new dams, by conversion of rain forests to cropland, or by sea level rise due to global warming) as well as those who are advantaged.

These general ideas allow one to understand why existing systems of national accounts (e.g. GNP and GDP measures) exhibit so many difficulties when they are applied to environmental planning. Three particular difficulties of conventional accounting deserve examination (Anderson 1991): (1) failure adequately to separate 'goods' from 'bads'; (2) uncertainty; and (3) over-reliance on single attribute (monetary) measures of value.

GNP measures do not distinguish between Goods and Bads. Medical care resulting from air pollution adds to GNP. So do the costs of restoration following storms or earthquakes, the costs of pollution control equipment, and investments made to preserve species. One can imagine a society with an ever-increasing standard of living as measured by dollar income, and yet an ever diminishing quality of life (Cobb 1989).

Information: national accounting systems. At present, national accounts rely on the notion that all important values can be compared and aggregated by expressing them in monetary terms. The key assumption is that monetary measures can capture all relevant senses of value. A controversial question for environmental accounting is whether to adopt this perspective.

Experience thus far suggests that ecological systems are far too complex to be usefully described by any single measure (Ludwig *et al.* 1993). Efforts to do so obscure how much is known. They fog issues and muddle real differences of perspective. Environmental accounting systems should illuminate diverse goals. They should be able to reflect the views of those who believe that technical ingenuity and 'progress' will provide future generations with undreamed – of opportunities and few adverse side-effects. And those who believe our generation is depleting the world of irreplaceable resources and impoverishing our

descendants and the rest of the world should also be able to employ economic concepts to illuminate their views.

To summarize, present accounting systems:

- include embedded assumptions about what is important now, what will be important in the future, and the nature of change;
- tend to emphasize quantities that enter into commerce;
- emphasize flow variables over stocks;
- often do a poor job of representing uncertainty;
- have difficulty dealing with 'side effects' or 'externalities' especially those which are uncertain in character and delayed in time;
- are not well suited to coping with limits, dynamic effects, irreversibilities (like loss of species), or characteristics that cannot be represented in monetary units.

What appears good to one person or group may appear bad to another. Further, values can and do change with knowledge and experience, and from one generation to another. Accounting systems must be responsive to this diversity. While no satisfactory system of environmental accounts is as yet in sight, it is possible to suggest some directions:

- Many kinds of measurement units should be included. Biological, geological, physical and equity indicators should figure prominently.
- indicators should be but one of many measures and they should not be determinative, as with benefit-cost analysis.
- A large range of spatial and temporal scales should be accommodated along with different levels of aggregation.
- Uncertainty should be explicitly addressed.
- There should be capability to represent many perspectives, including minority views.
- Environmental accounting systems should be linked to specific conceptual models. Data cannot be comprehended except in the context of logical structures. An example is the connection between anthropogenic carbon emission and climate. Without a conceptual framework (in this case climate models) data in this area would be incomprehensible.
- Optimization model approaches have serious limitations.
- Environmental accounting systems should be dynamic, flexible and adaptive. They should be structured so that their internal organization can be updated as new indicators and information become available.

Key Messages

- Virtually every decision people make can have an influence on biodiversity, either positive or negative. Losses in biodiversity can affect the sustainability of society. Continued policy failures can lead to domestic turmoil.
- Loss of biodiversity at the hands of people will continue and even accelerate, because the amount of space on our planet and the natural resource base are fixed, but both consumption and human population are expanding, leading inevitably to increasing pressure on limited resources. Therefore, these resources need to be managed more effectively, and the policies adopted need to be supportive of the Convention on Biological Diversity.
- Although it is by no means clear whether poverty, with its pressures to survive, or affluence, with its pressures to consume, ultimately leads to greater loss of biodiversity, it is obvious that the rural poor cannot conserve their biological resources if this is in conflict with their immediate survival needs.
- Human activity is not necessarily incompatible with the maintenance of biodiversity, and many human actions tend to foster greater biodiversity (especially components which people consider desirable). However, some important components of biodiversity are most likely to prosper in areas that are remote from human influence; where extreme environmental conditions prevail; or are associated with conditions provided by humans (for example, within protected areas, agricultural lands, and other systems that are managed by people).
- Tropical islands can provide a preview of the environmental situation that is likely to become more prevalent on the world's continents in the future. These islands typically have high population densities, exhibit highly fragmented landscapes, and have already experienced significant extinction events. On the other hand, their landscapes are now enriched by the addition of imported plants and animals that form new combinations of communities and ecosystems (which sometimes replace native species and communities which may have been unique in the world).
- Economics provides a useful perspective for understanding human relationships with biodiversity. Property rights is a crucial element in understanding why biodiversity is lost. Goods can be bought and sold only when property rights to them are well defined, where the seller truly owns the goods, and has the right to transfer these goods to others. Biodiversity, on the other hand, is a public good that is provided to everyone, rather like law and order and defense. Market economies, if left to themselves, typically under-provide public goods. Thus property rights work well for bread as a private good, but much less well for a public good such as genetic variation in wheat types. The full social benefits of tigers, rhinos, portfolios of germplasm, marine resources of a global commons, and so forth, are public goods beyond appropriation by markets, even when market value is fully enhanced by all the devices of the law. Therefore, new policies are required which help enable public goods to be managed for the benefit of society.

Efforts to develop alternative environmental accounting systems are at an early stage, but the process of refining existing accounts and proposing alternative accounts is helping to sharpen discourse and illuminate critical assumptions and issues.

11.2.3.6 Inequity in the ownership, management and flow of benefits from both the use and conservation of biological resources

In most countries, ownership and control of land and biotic resources, and all the benefits they confer, are distributed in ways that work against biodiversity conservation and sustainable living. The rapid depletion of species and the destruction of habitats are the norm in many countries where a minority of the population owns or controls most of the land. Profits from logging or fishing flow to the few,

while the local communities dependent on the continued production of the resources pay the price (see also 11.2.3.1.3).

A second problem arises from the concentration of resource control and responsibility for environmental policy decisions primarily in the hands of urban men. In many societies women manage the environment and possess far greater knowledge of biodiversity's value to farming and health.

A third issue is the way international trade, debt and technology transfer policies and practices foster inequities that resemble – and often reinforce – those found within nations. By 1988, developing countries were transferring \$32.5 billion net to industrialized countries, excluding other implicit resource transfers not involving direct financial flows (United Nations 1989). (At the beginning of

the decade, \$42.6 billion had been flowing to developing countries.) Between 1986 and 1993 developing countries paid \$1253 billion to serve a growing foreign debt that reached around \$1550 billion in 1994 (IMF, 1994). If the developing countries continue to be shut out of markets, deprived of access to technology, and burdened with debt, they will have neither the means nor the incentive to conserve their resources for the future.

11.2.4 Conclusions

The major cause of biodiversity loss in recent historical times is human action, primarily land use that alters and degrades habitat to serve human needs (Pimm and Gilpin 1989; Freedman 1989). Yet the ability to forecast the impact of specific actions on biodiversity is not yet well developed, and practical techniques for conducting such analyses are at only a very preliminary stage (OTA 1987; Soulé and Kohm 1989). Machlis and Forester (1992) have pointed out that while a large number of conceptual and predictive models of the interactions between humans and nature exist, explicit models of biodiversity loss are sparse and incomplete. While many of the generic models treat ‘environmental change’ or ‘ecosystem alteration’ as the dependent variable, it is not at all clear that biodiversity loss can simply be substituted for these more general factors. Biodiversity loss is a special case of environmental change, and the socioeconomic factors that influence it may not have generic impacts. For example, biodiversity loss measured as a reduction in species richness may be so dependent upon the original number of species at a specific locale that certain generic models will fail to explain, much less predict, even the most dramatic levels of biodiversity loss. The importance of habitat in the preservation of biodiversity may suggest that spatial relationships at the local scale will play a more significant role in biodiversity models than, say, models of climate change.

However, it seems apparent that the issue of scale is crucial, as biodiversity loss is embedded in a complex human/environment system that operates at several hierarchical levels; socioeconomic factors important at one scale may be less important at another, and at each different scale, new variables and relationships may emerge as critical driving forces.

The driving forces of human-induced change will vary with the type of change involved, and forces that drive some changes may lessen others (Meyer and Turner 1992). For example, rising agricultural prices may provide an incentive for clearing forests, while also providing an incentive to adopt soil conservation measures. Second, the same kind of land-cover change can have different sources in different areas, with deforestation in some areas primarily for timber extraction, in others for shifting cultivation, and in others for establishment of plantations.

In the dynamics of underlying causes, no agreement yet exists on the level at which adequate explanation is achieved. For example, some may consider that deforestation by agricultural expansion is driven by population growth, while others would contend that agricultural expansion helps to cause population growth; others will suggest that population growth needs to be explained in terms of the socio-political and economic conditions that promote it. Ehrlich and Ehrlich (1990) have attempted to provide a single comprehensive approach to the question of driving forces, using the equation $I = PAT$ where I represents environmental impact, as the product of P (population), A (affluence) and T (technology). Thus, human impact is a product of the number of people, the level at which they consume, and the character of material and energy flows in production and consumption. Meyer and Turner (1992) have pointed out that this formula suffers from the handicap of a mismatch between its categories of driving forces and the categories customarily used in the social sciences. Neither ‘affluence’ nor ‘technology’ is associated with a substantial body of social science theory.

Today’s pressures on the natural world mean that the genetic diversity of many species is being reduced because the total sizes of populations are decreasing and they are often being split into small, widely separated, subgroups which cannot interbreed. Others might argue that this is one of the processes of speciation, with humans serving as a new isolating mechanism.

11.3 Information requirements for the sustainable use of biodiversity

11.3.1 Introduction

Effective action must be based on accurate information, and the more widely shared the information, the more likely it is that individuals and institutions will agree on the definition of problems and solutions. However, the current state of knowledge is still largely inadequate to evaluate precisely what are the impacts of human activities in different ecosystems, and to understand what are the relationships between economic activities, development and conservation of biodiversity. Gaps in knowledge may have at least three origins.

First, the lack of information resulting from an insufficient research effort, especially for the inventory of species and ecosystems (see 11.3.2.4), for understanding how components of ecosystems fit together and interact with one another, for information on traditional use and knowledge of biodiversity, and for changes in ecosystem use. A significant increase in funding and man-power could fill most of these gaps. However, while some scientists argue that until we understand the natural environment, it will be difficult to understand how human societies interact

with these systems, it is not realistic to wait for many years for conservation action. What to do in a situation of uncertainty?

The second major source of gaps derives from the complexity of the natural environment and the complexity of the interactions between human societies, their activities and the natural world. Natural and social sciences evolved independently, but better interaction between them is needed to understand the nature and strength of their relationships. The long-term preservation of biodiversity depends on management strategies and modes of development, but it is very difficult to forecast changes in human behaviour. This uncertainty makes it difficult to predict changes in the environment and the expected consequences for biodiversity, and it reinforces the need to monitor biodiversity carefully in order to respond with corrective action.

The third set of gaps involves access to information and how to use what we already know. How can technological solutions be applied on a large scale? While useful concepts such as 'sustainable development' and 'integrated management' are available, we need guidelines for action, supported by reliable observations and experiences. The effective implementation of biodiversity action plans relies on improved methodologies and tools.

In general, research must be expanded and strengthened to improve our understanding of biodiversity and its potential role in building sustainable human societies. We need to understand a great deal more about how, why and where human activities affect biodiversity, in order to provide accurate information to politicians and decision-makers. Research must serve to inform, supplement and improve conservation efforts, but it should not be a substitute for immediate action. However, even with a complete inventory of the status of global biodiversity, and a perfect understanding of the relationship between human activity and biodiversity, we will still face the problem of how to control destructive human behaviour.

11.3.2 Monitoring biodiversity, its use, and changes in natural and managed ecosystems

Different parts of the world are being subjected to varying degrees of transformation. Some areas have been altered by humans over long periods, while in other regions human influence has been moderate. The response to disturbance varies greatly from one ecosystem to another, so we need to monitor and document changes in biodiversity resulting from climatic changes or human activities in a variety of natural and managed ecosystems, and in different climatic zones (Solbrig 1991). To detect, measure and assess changes in the status of biological diversity, appropriate monitoring methods should employ specific indicators of biodiversity attributes, as well as indicators of

socioeconomic changes. One of the greatest difficulties is to distinguish the effects of natural fluctuations and changes from the effects of human-made disturbances. Another question still partly unanswered is what exactly should be monitored. Distribution and abundance of selected species? Changes in ecosystem structure, species composition, functions and processes? Distribution and area of different land-use classes, habitats, biotopes, ecosystems?

11.3.2.1 Long-term monitoring

Most of the questions asked of scientists by managers concern our ability to detect changes in the physical, chemical or biological state of the environment, and to distinguish cause from effect. We need data sets from good, regional, long-term monitoring to provide decision-makers with convincing data on environmental changes due to adverse impact (see Section 5). The selection of sites for long-term monitoring depends on the questions to be investigated, but in selecting sites, a good knowledge of their management history is most relevant to an understanding of the processes of change. However, long-term data collection programmes face problems of the continuity of the variables measured, continuity of funding, and comparability of data as analytical methods change.

Monitoring programmes are also faced with major difficulties in the interpretation of data. For example, species extinctions and ecosystem changes do not always result from a single disturbance but rather from the cumulative effects of many different disturbances, and it is not always easy to determine the relative importance of the different factors. Moreover, some environmental factors change gradually over time, while others create short-lived but major disturbances (such as acute pollution, volcanic eruption, or occasional extremes in climate) that could be very important determinants of long-term changes. If they are not recorded, the subsequent data sets will probably be difficult to understand. Moreover, ecological processes operate at a broader range of temporal and spatial scales than is typically addressed in ecological studies, and long-term research reveals processes and events that have often been invisible in the short term. Such is the case for slow changes occurring over years or decades, which are hidden in the so-called 'invisible present' (Magnuson 1990), i.e. we frequently observe the response of an ecological system to a cause that occurred before monitoring began, and in most impact studies we are seeing the transition of the system rather than the new state it is likely to reach.

A major issue in monitoring programmes, as well as in designing restoration programmes, is to identify a baseline reference situation with which to compare the collected data. Any impact study should refer to a standard 'natural' or 'non-perturbed' ecosystem. However, the 'natural community' has in fact already been disturbed virtually

everywhere and trying to ascertain its original characteristics is a risky task. What is a 'healthy' system which should serve as reference (Loehle 1991), and how to evaluate its 'integrity', are key questions for ecologists and managers (Woodley *et al.* 1993). The relevant normative goal of human–environmental relationships is to maintain the integrity of combined natural/cultural ecosystems. Natural and social scientists should collaborate in the design and execution of long-term pilot studies of ecosystem integrity in catchment areas that include human settlements, and not only relatively simple 'natural' ecosystems which have usually only recently excluded human occupation.

11.3.2.2 *Monitoring the rehabilitation of degraded ecosystems*

As populations increase, the proportion of modified land is likely to rise, and in areas of severe land shortage, the management of such lands will become a matter of significant concern. However, lands degraded by over-exploitation have received little attention compared with natural systems, and there is now a growing need to improve the scientific understanding on which the effective management of degraded ecosystems can be based.

Rehabilitation describes a management strategy designed to arrest the degradation of landscapes. It includes restoration, which aims to reinstate entire communities of organisms closely similar to those occurring in idealized natural systems. Research needs can focus on describing alternative methods for rehabilitation, including re-seeding of native species, plantations of exotics, etc. More information is required about the genetic structure, biology and ecological requirements of many plants or animals, and their potential for rehabilitating degraded sites. Research is needed on what species attributes would ensure successful invasion of degraded systems, and what is the most cost-effective way of screening the native or exotic flora and fauna to locate candidate species for (re)introduction (Soulé and Khom 1989). We also need to study and compare the rate of ecosystem recovery when submitted to natural and anthropogenic disturbance regimes, and to identify the impacts of different prior land uses on restoration potential, identifying the principal factors that affect restoration in different systems (USNRC 1992).

11.3.2.3 *Species introductions*

The devastating effects of introduced rats, pigs, cats or rabbits to oceanic islands are widely documented, but in most cases we know little about the impact of introductions on native communities and ecosystems when they do not result in ecological catastrophes. The list of plant and animal introductions is enormous and the future promises a continuing spread of exotic species. However, while the introduction of species has been encouraged all around the

world for centuries, both by managers and by scientists, many ecologists today are increasingly worried about their impacts.

Are introductions really a game of chance? Probably not, but we do not know the rules of the game. Many ecologists, more or less intuitively, claim that the introduction of exotics is risky, and Chapters 11.1 and 11.2 have mentioned cases that may be considered ecological disasters. Conversely, there are also examples of assumed success, and managers are very cautiously optimistic of using new species to improve agriculture or fisheries production, especially using biotechnology to produce genetically modified organisms.

However, one of the major problems with species introductions is their irreversibility, at least at human time-scales. Once introduced and established, it is almost impossible, given current technology, to eradicate an exotic species from a large ecosystem. Therefore, there is great need for a careful assessment of past experiences to provide general, scientifically based guidelines and policies about species introductions, taking into account both the potential ecological values and the economic values of these introductions. It is also essential to evaluate the potential long-term detrimental effects of introduced exotic species, under controlled conditions, and before their release.

Introducing genetically modified organisms presents unique risks because laboratory results alone provide a poor guide to their behaviour, ecological impacts and potential socioeconomic effects. Accordingly, strict Codes of Conduct related to the release of such organisms are urgently needed in all countries and at the international level (WRI *et al.* 1992).

11.3.2.4 *Inventory and data bases*

To assess long-term changes in biodiversity, a basic prerequisite is a good knowledge of species and their distributions in space – the task of biogeography. However, the inventory and descriptive phase of biodiversity is far from complete, and present-day estimates of the number of species on Earth is a matter of debate, because our knowledge of the species and their distribution is inadequate. The world database is still of variable quality, and there is a shortage of data for many taxonomic groups. There is an urgent need to accelerate collection along with description of organisms, particularly those that are ecologically important and threatened by human activities. A global network of systematists should be established to accelerate the inventory of global biodiversity through improved systematic practices (Solbrig 1991; Bisby 1994).

An effort should also be made to develop new and innovative ways of exchanging biological information, such as the use of computerized relational biological databases, so that it is possible to establish in-country user-friendly biodiversity databases for use in decision-making and for

analysis of trends. This is already under way by groups such as the World Conservation Monitoring Centre, and many of these efforts are discussed in Bisby *et al.* (1993).

11.3.3 Strengthening social science research and the connections between biological and social processes

The fundamental causes of the observed attrition of natural biological systems are rooted in the contemporary human condition, involving interactions between social and ecological processes. Therefore, the conservation of biodiversity must focus largely on economics, sociology and political science. Soulé (1991) recognized seven key factors to which our present knowledge does not allow definite answers:

- Population growth: what is the relationship between population growth and impact on biodiversity?
- Poverty: what is the impact of poverty on biodiversity? Conversely, what is the impact of wealth on biodiversity?
- Misperception of time scale: what is the impact on biodiversity of the short-term mentality of many governments and businessmen?
- Anthropocentrism: if a new ethic and a revolutionary change in human consciousness are necessary to support conservation purposes, why is there a general lack of support for non-utilitarian causes, and why are current cultural values usually human-centred?
- Cultural transitions: which socio-cultural situations foster loss of biodiversity and which foster conservation?
- Economics: what kinds of economic instruments foster the loss of biodiversity and which foster conservation?
- Policy implementation: what is the impact of social and political instability on biodiversity?

Another causal factor, not mentioned by Soulé, is the lack of responsiveness of decision-makers at the national and international levels to local indicators of environmental degradation, including indigenous knowledge and observation of user groups.

11.3.3.1 Knowledge, innovations and practices of indigenous and local communities

Faiths, cultures and traditions give people their basic orientations toward the natural world and guide their actions. Nature has been considered (and is still considered) by many people as an obstacle to human purposes as well as the direct or indirect source of all the material necessities and comforts of human life. For instance, aquatic ecosystems are considered both as a reservoir of biological

resources (fish, shrimps) to be preserved, and as a reservoir of diseases (malaria, schistosomiasis, etc.) to be eradicated. This dilemma may explain why human attitudes to nature differ from culture to culture, and have changed over time. Their importance is often overlooked in conservation programmes, while people's commitment to conserving and sustainably using biodiversity springs from the human 'sense of place'. There is a need to understand better how ethical norms and religions condition human behaviour toward biodiversity.

During the last two decades, the link between biodiversity conservation and sustainable socio-economic development has been recognized. It appears that the interests of some human groups have been strongly linked to the prudent use of their resource base, and that they have evolved appropriate conservation practices based on some simple and approximate rules that have tended to ensure the long-term sustainability of the resource base. These rules may have been developed by a process of trial and error, with acceptance of practices that appeared to keep the resource base secure coupled with rejection of those practices that appeared to destroy the resource base.

There is a need to recognize the value of traditional knowledge, and subsequently to develop a mechanism for the appropriate protection of, and compensation for, such knowledge (UNEP 1994). This can be achieved through (1) a better knowledge of biological resources being exploited, as well as the full range of uses and values of these resources, and (2) compilation of available information with the support of a group of specialists. We must also identify and develop means to maintain traditional knowledge and to strengthen and develop indigenous and local community strategies for conservation and sustainable use of biodiversity, fully respecting their intellectual and cultural integrity and their own vision of development. This research should build a greater understanding of the relationship between biodiversity and local systems of knowledge and resource use, and should translate this understanding into useful policy (USNRC 1992).

11.3.3.2 Legal aspects

The position of biological diversity in national legal systems is one of the important judicial problems of today (de Klemm and Shine 1993). Plants and animals are objects whose degree of protection depends on the value they represent for human beings. Although well intentioned, this specifically anthropocentric view leads directly to the subordination of biological diversity, and to its sacrifice in spite of modern understanding of the advantages of conservation.

One major concern is the implementation of legal instruments developed nationally or internationally. Most treaties and conventions are not obligatory for the

countries, and their application is usually delayed. Attention must be given to structural problems that contribute to biodiversity loss, such as unequal trade relations that might conflict with the conservation of biodiversity, or the impact of debt on the exploitation of biodiversity (IUCN 1994).

To strengthen the position of biological diversity in our societies we should provide the guidelines of legal procedures and ethical considerations. We should accept biodiversity as a legal subject, and supply it with adequate rights. This could clarify the principle that biodiversity is not available for uncontrolled human use. However, this non-availability should not turn into an unrealistic conservation. Contrary to current custom, it would therefore become necessary to justify any interference with biodiversity, and to provide proof that human interests justify the damage caused to biodiversity.

To realize the objectives of the Biodiversity Convention, biodiversity concerns must be integrated into mainstream public policy and law governing the natural resource-based production sectors, such as forestry, fisheries and agriculture. Many existing legal frameworks, issues, obstacles, strategies and prospects are associated with this integration (Glowka *et al.* 1994). The precautionary principle is increasingly seen to be of great importance to the conservation of biological diversity. In international environmental soft law, it has emerged as a recognition of the uncertainty involved in impact assessments and management, and in the determination of the future consequences of present decisions. However, its translation into binding rules of law is particularly difficult, and a number of legal problems will have to be resolved (de Klemm and Shine 1993). Its implementation in fisheries management has been suggested and FAO is currently developing Guidelines for Responsible Fishing (García 1994).

A whole new area in the legal world is the question of intellectual property rights. While the convention affirms the right of states to require payment for the commercial use of genetic resources obtained from their territory, the formalization of such rights, equitable as it may seem, gives rise to considerable practical difficulties. How will it be possible to determine the true country of origin when the resource has a distribution range overlapping many countries? What sort of recourse will a country of origin have if the genetic material has been smuggled out of the country? (de Klemm and Shine 1993). Disputes are therefore bound to occur and difficult problems of proof may arise.

11.3.3.3 Economics and biodiversity

Natural resources are crucial to human welfare so there are strong interactions between ecological systems, economies and social systems (Arom *et al.* 1993). Biologists have in

general displayed concern for the health and persistence of ecosystems as a foundation for human well-being, but usually oversimplify the economic side of the relationship. Conversely, many economists ignore natural systems and resources while many of the critical questions at the ecology–society interface involve economics (Ehrlich 1989).

Despite past neglect of environmental problems and externalization of environmental costs, a few economists since the 1970s have taken a broader interest in environmental issues. Growing environmental problems have not abandoned the idea that maximizing human welfare is an inherent goal of economics, but the goal has been deprived of its exclusivity. This change was due largely to scientists who argued that there were limits to human population and development (Goodland *et al.* 1991). Fortunately, the pessimistic scenarios foreseen for instance by the ‘Club of Rome’ and others (Goldsmith *et al.* 1972), have not occurred, but the decisive question raised by debates about the ‘limits to growth’ is still unanswered: How large can the human population become and how long can it be sustained with the available resources? To achieve global sustainability, economists must extend their theoretical horizons and consider the environment in production costs (Hohl and Tisdell 1993).

A major challenge is to evaluate the biological consequences of economic activities and to develop appropriate economic models for the sustainable use of natural resources.

11.3.3.3.1 Contribution of wild species to local economies and to international trade. A central question in the effort to conserve biodiversity is how local people affect the biological diversity of the ecosystems they inhabit (USNRC 1992). In other words, how do local people use biological resources? Why? And what is the overall contribution of wild species to local economy? What are the incentives of local people to use ecological resources sustainably and how can these incentives be transferred from the ecosystem to the biosphere? The screening of plants and animals for features of potential use to mankind should also be accelerated, in order to identify organisms of potential benefit in agriculture and in the provision of environmental services. Particularly important in this regard are traditional drugs which can be used to treat diseases in communities that lack access to modern medicine because of its expense (USNRC 1992). However, results of this screening should benefit local people directly where traditional knowledge leads to the identification of a resource with broader value, and it should be protected through local control from non-sustainable exploitation.

International trade in wild species deals with living specimens (ornamental plants, ornamental fish, snakes, parrots, etc.) as well as dead specimens for collections (shells, insects, etc.). It also includes the trade in ivory,

rhino horns, skins, furs, bones, etc. Recent estimates put the annual turnover in the wildlife trade at US\$5 billion (Le Duc, 1990) (as mentioned in 11.2.3.4). In recent years serious efforts to control this trade have been made through the Convention in International Trade in Endangered Species of Wild Fauna and Flora (CITES), which came into force in 1975. However, as controls have become tighter and more effective, they have encouraged the development of sophisticated illegal networks.

While we have a substantial amount of data for some charismatic species, they are far from complete, and for many other species we have little information about the number of species and the individuals collected by such trade. We know that a significant trade exists, but the usual lack of customs expertise for the identification of imported specimens makes regulation difficult. Also, for most species, we do not know the consequences and long-term effects of massive harvesting on either the genetic diversity or the abundance of heavily exploited wild populations. Indeed, we do not know how to predict with accuracy the level of exploitation possible for many species before serious genetic erosion or species endangerment occurs.

Nevertheless, there is evidence that over-harvesting is the principal threat to certain species (the illegal trade in rhino horn has been almost entirely responsible for the drastic decline of the black rhinoceros in Africa during recent decades according to Cumming *et al.* 1990), and a significant contributory threat to many others, especially rare species and those of limited distribution. The rareness of a species adds dramatically to its value in this trade, and several species have been driven close to extinction by collectors (Jenkins and Oldfield 1992). Appendix I of CITES lists over 600 threatened species of animals and plants that are, or might be, affected by trade (Burgess 1994).

11.3.3.3.2 How to value what we have? Natural ecosystems have been considered as unproductive areas whose benefits could be realized only by conversion to some other use. Decisions on land and water uses, for example, have a great impact on biodiversity but political considerations are often paramount in these decisions when the value of biodiversity is introduced as a major component in the evaluation of alternative land/water uses. Many systems have been greatly altered because their value to society was not adequately demonstrated, and because evaluations favoured short-term benefits.

Valuation is therefore a fundamental step in informing planners and resource managers about the economic importance of biodiversity in national development objectives, and in demonstrating the importance of different areas for the biological resources they contain (Ehrenfeld 1988). Current methods of evaluation used in decision-making, such as cost-benefit analysis,

inadequately reflect the true environmental and socioeconomic values of natural resources and ecosystems. The economic values of natural biological resources are poorly understood and a variety of methods have been devised for assigning values (de Groot 1992; Desaiques and Point 1993; Pearce and Moran 1994). Some methods have been developed to enumerate values of individual species, but not entire ecosystems. Moreover, the methodologies for economic valuation of environmental functions are not universally agreed. Economists have developed various techniques to capture direct use values, indirect use values and option values, but techniques for reflecting the non-use values involving bequest, cultural and heritage attributes are in early stages of development. Empirical problems include the difficulty of estimating the costs of environmental trends (such as the accumulation of greenhouse gases) in the presence of great uncertainty over their predicted impact (see Section 12 for a detailed review).

Another need is to determine how to protect an area and its species and how much it will cost. For example, conserving biodiversity in its present condition would require more funds than are assumed to be available in the near future. The need to provide economic incentives for the conservation of biodiversity is generally recognized – at the international or national level (by transfer of resources), or locally by ensuring that local communities benefit from the biological diversity of their regions (McNeely 1988). To achieve this goal, it would be useful to document and publicize cases in which incentive systems have successfully conserved biodiversity; determine how to adjust incentive systems to achieve a more efficient and sustainable allocation of resources; determine how incentives can be used in biodiversity restoration efforts in degraded systems; identify institutional constraints on the implementation of incentive systems at the local and national level, and develop strategies for the elimination or mitigation of these constraints (USNRC 1992). If we assume that environmental awareness evolved gradually in different countries, then studying the way these changes occurred, and working out how they could be enhanced in developing countries, is probably the type of research that is at the right level of resolution (global conservation) and could have far-reaching ramifications.

A major problem is therefore to find approaches, agreeable to economists and non-economists alike, on valuation methodologies that capture across cultures the consumptive and non-consumptive values of biological diversity. Research in environmental economics needs to be strengthened. Uncertainty over the local, national and international economic value of biological resources and biodiversity invites policy-makers to discount both and to avoid conservation investments when other budget priorities offer more readily quantifiable benefits. If the costs of resource degradation and the benefits of saving and

using biodiversity were better understood, better conservation incentives for resource users could be designed (WRI, IUCN and UNEP 1992). Moreover, while the valuation of the economic contribution of regulatory environmental functions, particularly in developing countries, is still in its infancy, findings to date indicate that the indirect benefits of these functions are of a magnitude that may rival even the direct benefits of sustainable use of natural systems (Aylward and Barbier 1992; de Groot 1992).

11.3.3.3.3 Managing trade and having biodiversity too. Never before has human society engaged in trading such a diversity of commodities, on such a geographical scale and volume, as currently occur. Further, as a result of liberalization measures contained in the recently concluded GATT negotiations, trade is likely to expand. The overall impact on biological resources from increased production, consumption, exchange and transportation of goods and services is difficult to foresee.

A major question is how much increase in consumption and production we can allow without compromising the sustainability of the biosphere. What is the optimum core of biological wealth necessary to maintain the present state of global production without impairing future options? For these questions, there is presently no definite answer.

Another major concern is that of how the global community can direct international trade to deliver economic progress without impairing economic sustainability (Goodland *et al.* 1991). Trade is market-driven, and markets function best when the regulator's 'command and control' measures are supportive of the development of free trade rules, practices and related infrastructures. However, trade in itself is environment-blind. The invisible hand of the market does not have any adequate self-corrective mechanism to consider biological losses and reduction of biological diversity. This would imply that some degree of 'command and control' will be necessary. Ecologically fragile wetlands can be transformed into shrimp farms in the short run, but without enlightened management, care and regulatory supervision, these areas may be destroyed. Individual nation states have considerable experience in using regulatory and market-based instruments to promote environmental objectives. However, there is no prior experience of fusing global trade and environmental goals.

11.3.4 Toward sustainable use of resources and

ecosystems: the need for new management options

Modern societies seem unable to halt, much less reverse, the ongoing depletion of resources and degradation of the environment. Resource management has not always been designed for the sustainable use of resources, but for their efficient utilization as if they were boundless. Ecosystem management according to ecological principles alone, is

not sufficient. Increasing pressure to use natural resources for a variety of purposes, combined with the increasing democratization of resource allocation decisions, has made social values an important component in the management process. There is an urgent need to improve the link between ecological science and public perception and values. We must develop a new resource and ecosystem management science that is better adapted to serve the needs of ecological sustainability. Sustainability concepts are increasingly important to policy-makers around the world, but it is not easy to devise better development models because poverty is a major cause of habitat and biodiversity loss in developing countries. Actions to alleviate the loss of biodiversity must address the socioeconomic causes of poverty (Schweitzer 1992).

11.3.4.1 Ecosystems management

It is likely that one of the major environmental concerns in the 2000s will be the preservation of biodiversity in the context of sustainable development, and that is closely related to future options for the management of lands and waters.

A major factor of success in designing sustainable exploitation systems is the cooperative capacity of the local community, and its ability to design and implement management plans. Research is needed to help communities obtain the greatest benefit from any land or water over which they have legal rights, and to identify ways to integrate the knowledge, innovations and practices of indigenous and local communities into modern management practices. How do different land management systems, such as individual property and common property, affect the use and protection of natural resources? What combinations of extensive and intensive land and water use achieve satisfactory sustainable returns to people while conserving biological diversity? For instance, at the level of the forest people, more research is needed to determine how they and their traditional land-use practices are affected by different forms of rain forest management, e.g. alternative logging practices, introduction of plantations, conversion of cleared areas to intensive agroforestry. This also emphasizes the need to assess local perceptions of proposed modes of development (Schreckenbergh and Hadley 1991). There is a major gap in our knowledge of the effectiveness of alternative use/management strategies for biodiversity conservation.

11.3.4.2 Living resources management

The well-being of human populations depends on the availability of a variety of renewable resources which may be utilized either sustainably, at rates that permit harvests at a given level over a long time, or exhaustively, at rates which in the long run lead to a decline in the total stocks. Recognition that our natural resources are not currently

managed on a sustainable basis may lead to the conclusion that further loss of biological diversity will reduce our future options for sustainable biological resource management (Cairns and Lackey 1992).

Resource management options have ecological, socioeconomic and political constraints (Clark 1989). Conflicts, or at least competition, between protection of biodiversity and production of resources are likely to occur; and what might be in the interest of society is not always in the best interest of individuals. There is a conspicuous paucity of examples showing how both traditional and modern societies perceive, value and conserve biological diversity while successfully using natural resources in a sustainable manner (exceptions include a number of cases documented in Johannes 1978; McCay and Acheson 1987; Berkes 1989; Bromley 1992). Achieving a balance between resource use and conservation, accepted as mutual goals in technological societies, has largely failed. Ethnobiological research is needed to design more effective and locally acceptable conservation and management plans (Soulé and Khom 1989). In fact, rural populations have had the capacity throughout their history to manage their resources for a sustainable yield while the ability of primitive humans to exterminate a vast array of prey species is also well documented. It is only in recent times (beginning in the colonial period but greatly accelerated after 1950) that traditional systems for managing resources have been replaced by government agencies and have proved to be less efficient, or at least not as successful as they should be.

This situation can be illustrated by fisheries management in inland waters. After the Second World War, the European ideas of rational fisheries management were assumed to be the only universal solution for sustainable use of fish stocks. Most policies for the sustainable management of fish stocks derive from the concepts of equilibrium population dynamics and stock assessment, and aim to achieve a level of fishing effort at which the stock or population is conserved at its level of maximum sustainable yield. Although the principle of Maximum Sustained Yield has been challenged, it is still accepted as one of the main bases for management. Despite the apparent capacity to determine the levels of harvest needed to conserve fish stocks, there has been an almost universal failure to do so. This failure may lie in part in the shortcomings of scientific advice, but for the major part lies in the difficulties of applying coherent management strategies for political and sociological reasons (Welcomme 1992). Efforts at central fisheries management during the last few decades have not been especially cost-effective, and serious consideration therefore needs to be given to reinstating community-based, traditional-type management structures.

For tropical forests, agroforestry is a collective name for land-use systems and technologies in which woody

perennials (trees, shrubs, palms, bamboos, etc.) are combined on the same management unit with herbaceous crops and/or animals, in some form of spatial arrangement or temporal sequence (Schreckenberg and Hadley 1991). Agroforestry is not a new technology and it has often been used traditionally in different ways in many parts of the world, but farmers have abandoned such forest use because of inappropriate land or forest tenure systems. Combined with modern agricultural and forestry techniques, traditional agroforestry is often stated as one of the most successful approaches to producing tropical hardwood in a sustainable way, but it cannot be an answer to the demand in the developed world. At present, additional research is needed to allow a progressive change in land use from traditional shifting cultivation or extractive forestry to more intensive agroforestry (Schreckenberg and Hadley 1991). Several initiatives are also under way to develop systems for sustainable forest management in all types of forest in the world, and to agree on a system of labelling sustainably produced timber.

To achieve the sustainable use of environmental systems, there is an increasing need for new resource management systems. Should they be based on the resource management techniques of the industrialized countries, or should they be developed by rehabilitating and adapting 'indigenous' resource management systems and upgrading traditional local-level institutions? Is there any way to integrate the scientific and traditional systems? These are the central questions that must be answered in order to propose development models that take care of the environment and serve the needs of the people who use its biological resources. The only answer to this type of problem is to test different systems and discover what works. This is a new challenge because, until recently, scientists and policy-makers knew little about traditional management systems and accorded them little credibility.

We therefore need to conserve the diversity of traditional resource management practices and systems if we want to construct a new resource management science better adapted to the real world. The rejection of the monolithic scientific vision of resource management does not mean the overall rejection of science. The task is to develop a flexible approach by conserving what is useful in science. Ecology is in a unique position to be the cornerstone of a new science of resource management that synthesizes the best of the old and new wisdom towards a more sustainable future. But ecology would first have to extricate itself from the older utilitarian, 'control over nature' tradition of resource management (Gadgil and Berkes 1991).

What would be the reaction of a system in a case of reduced pressure on biological resources? We have little experience in this field, even if a great deal of experience has been gained in nature management systems during the last decade.

11.3.4.3 *The question of common property of natural resources*

The use of the term 'common property' has been controversial. For some scientists it means resources that are not amenable to private appropriation: they are free goods, not owned by anyone, such as marine resources, including fisheries. As a result, they are open-access and freely available to any user. An alternative view considers that the term 'common property' should be restricted to communally owned resources that are managed through communal arrangements for allocation among co-owners.

The 'tragedy of the commons' model (see 11.1.7 and 11.2.3) still persists in the conventional wisdom of many resource managers, and is also dominant in models of development exported to Third World countries. It led a generation of fishery managers and other resource managers to believe that absolute governmental controls needed to be established over both the resource and the user, and blinded them to the possibility of managers and resource users working together, rather than against one another. However, valuable natural resources are almost never open-access but are managed under traditional rules. Many case studies indicate that co-operation for communal interest more frequently occurs (Berkes 1989). Recent literature on common property rejects a deterministic 'tragedy of the commons' (Ostrom 1990; Stevenson 1991). The common property approach reverses the traditional emphasis of resource management, which has been on the resource rather than on the people, and starts with an analysis of the local property rights regime.

For some authors, appropriation is not property (Weber and Reveret 1993). The appropriation of a resource or an ecosystem may be understood under five components: (1) *representations*: the way each society perceives nature; part of the group culture; (2) *uses*: the use of natural resources is not always dictated by economic purposes; taboos exist everywhere; (3) *access to resource and control of access*: access is often regulated by customary institutions, myths, historical rights or traditional regulations, and may be individual or collective, permanent or temporary; (4) *transfer modalities*: that is, the way rights are transferred from one generation to another; (5) *re-partition and sharing*: the resource, or the benefit of the resource, may be distributed amongst all individuals or according to social status.

More research is needed on a global analysis of appropriation and use regimes. They are not well known partly because of the confusion between common resources and open access, though analyses of the management of common resources are becoming more numerous (Berkes *et al.* 1989; Bromley and Cernea 1989). However, before we consider new resource management systems we need to know the extant systems and understand the choices behind them.

11.3.4.4 *Predicting the consequences of social and economic changes on biological diversity*

One of the major challenges is to understand and adapt ourselves to natural, economic and political variabilities (Henry 1990), and to develop a flexible and adaptative approach to management. We can have a greater impact on the way people are using resources than we can on the resources themselves. An increasing population pressure is likely to occur, but we do not know to what extent. What kind of changes should we expect in consumption? How do groups extrapolate the future use of biological resources, and how do use rates change as biological, social, economic and cultural factors change? Is it possible to forecast future social behaviour and political options and/or is it feasible? There are so many unanswered questions about the future of humanity that it is difficult to forecast the future of biodiversity in relation to human needs and expectations. However, we need urgently to reinforce collaborations between social and biological sciences to gather at least enough information not to be unprepared.

11.3.4.5 *Knowledge-based systems*

Models of the dynamics of biodiversity under the impacts of natural and human-induced disturbances might provide a better way of managing ecosystems and resources. However, models built for explanation or prediction have not been very successful when applied to whole ecosystems.

A subsidiary goal of modelling activities could be to combine the various rules and generalizations developed through the long experience of ecologists and resource managers to make them available in a systematic way. They could then be applied to situations where less experienced managers may be faced with problems of making decisions with inadequate data. Such 'expert' systems do not provide definitive answers, but may act as a reminder of some of the principles that need to be considered and some of the interactions that might occur.

11.3.4.6 *Development and transfer of technologies relevant to the sustainable use of biological diversity*

One of the most consistent of the Agenda 21 themes, and one of the most intractable of issues, concerns access to technology (Rath and Herbert-Copley 1993). Among the proposals under consideration are: to increase the flow of information about environmentally friendly technologies; to increase industrial self-regulation; to increase the importance of markets in allocating values; and to promote improvements in environmental performance of industry in the South. This issue was widely discussed during the intergovernmental meeting of scientific experts held in Mexico in 1994 (UNEP 1994). It ranges from environmental impact assessment techniques to ecosystem

management techniques and integrated land use, biotechnologies, new and renewable sources of energy techniques, less wasteful lifestyles, consumption and production patterns, family planning techniques and economic and financial instruments.

The issue of access to technologies is about how to develop endogenous capacity to assess, adopt, manage and apply environmentally improved technologies. However, there are difficulties in identifying appropriate kinds of 'clean' or environmentally sound technologies to promote in developing countries. Environmental sustainability has not been a major consideration among mainstream innovation policy and management researchers (Winn and Roome 1993), and the literature on 'green' innovation policies is relatively small and dispersed among the literature on environmental management, environmental economics, risk assessment and economics of innovation.

Much of the literature on environmentally sound industrial innovation suffers from the difficulty of identifying and describing those variables linking the technical and social dimensions that are accessible to management, policy or political interventions. Mechanisms and instruments of deliberate social choice, especially ones that are feasible under regimes of democratic governance, are a relatively unknown part of the non-market selection environment.

11.4 Future prospects

11.4.1 Introduction

The world is an uncertain place. A strong interest remains in understanding what might take place in the future, although science has largely assumed the role of fortune-teller. However, with our limited understanding of the biotic and abiotic systems of the Earth and our even more limited understanding of human behaviours and cultures, forecasting is at best an inexact science. In fact, it is unclear to what extent our evolving understanding of systems can accurately 'back-cast' (*sensu* Kates *et al.* 1990), let alone forecast. Furthermore, predictions of the future vary depending on the forecaster's culture, religion, experience and temperament.

Modern fortune-tellers can be distributed along a spectrum with the 'Malthusian pessimists' at one end and the 'technological optimists' at the other (Goodwin 1994). The Malthusians tend to think it very likely that human civilization will collapse and human life, if it goes on at all, will return to the sort that Thomas Hobbes characterized as 'solitary, poor, nasty, brutish and short'. According to this position, no group of inventions or investments can permit us to continue living in the style, and at the level of material affluence, taken for granted by industrial societies today. We have so harmed the natural environment that ecological and economic collapse are inevitable, resulting

in the collapse of populations and civilizations, and perhaps followed by a regrouping at a much lower level of resource use and civilization. The Club of Rome report *The Limits to Growth* (1972), for example, predicted that population growth, resource exhaustion and pollution would bring about the collapse of human society by the early twenty-first century.

At the other extreme, technological optimists speculate that technological advances will rescue us, and that an ever-improving base of material well-being will continue to provide humanity with the option of continuing its experiments in freedom, justice and understanding. Many see no need to tamper with consumer behaviour, believing that any shortcomings of today's energy economy can be modified on the supply side. Simon and Kahn (1984) argue that the twenty-first century will indeed bring higher living standards and reduced human impacts on the environment as a result of technological advance and policy innovation.

Given the many possible and feasible views of the future, Goodwin (1994) suggests that a sensible course of action would be the following:

1. Given the lack of credibility attached to the predictions of either end of the spectrum, we need to prepare for many kinds of futures simultaneously – including that predicted by the pessimists and that to which the optimists look forward.
2. We should try to maximize the possibility that our preferred set of possibilities is realized, while taking steps to ensure against even a small probability of the most pessimistic scenarios being realized.
3. We should continue to refine our understanding of the competing predictions, both by adding to our knowledge about the events that will determine the relevant characteristics of the future, and by familiarizing ourselves with the terms of debate over why these events should lead one way or the other.

Speculation about and preparation for the future have necessarily taken place on two related but distinct dimensions. The first involves understanding the degree to which past human actions have set in motion irreversible and on-going change in the natural and physical environments, altering the range of options faced by human communities. The second involves the capacity of human societies to understand, adapt and respond to environmental change, a function of the cultural, social, economic and political contexts in which they operate.

11.4.2 Trends

11.4.2.1 Population and resources

Optimistic as well as pessimistic forecasters of the world's future recognize increasing demand by expanding human

populations as a source of immense stress on biotic and abiotic resources and systems. A key factor in assessing future demand is our ability to predict accurately population size decades in the future. The remarkably accurate prediction of today's population by demographers in the early 1970s is a tribute to their technical skill (McNeely and Ness 1995) and should give us some confidence in current estimates of global population over the next few decades.

The world population in 1990 has been estimated as 5.29 billion, 78% occurring in LDC (less developed countries, effectively all countries excluding Europe, North America, Japan, Australia and New Zealand). The significant increases anticipated in total world population in the coming decades are largely uncontended and two sophisticated analyses arrive at similar 'middle' scenarios: by 2025 world population will stand at 8.5–9.0 billion people (UN figures, quoted by WRI, UNEP, UNDP 1990; Lutz *et al.* 1993). The latter authors used three components of population change – fertility, mortality and migration – and using various estimates of the range that these three components could realistically take, developed nine population scenarios. Although these resulted in a wide range of possible outcomes, three conclusions were consistent:

- World population will continue to grow and by 2030 will have increased by at least 50%, and may even have doubled in size. The 'central' scenario suggests an increase of 80% with a population of 9.5 billion (Table 11.4-1).
- Developing countries will account for a greater share of the world population and by 2030 will have increased from 78% of world population in 1990 to 86%. Under all scenarios, Africa's share of the population will increase most rapidly (the central scenario estimates Africa's population will increase from 12% of world population in 1990 to 19% in 2030 and 26% in 2100 (Table 11.4-1).
- All populations will become older and the more rapidly fertility declines the faster populations will age.

The world's population is likely to double in the next 60 years, even if fertility rates fall in virtually every developing country (Jolly and Torrey 1993). If the demographers' consensus holds true, we are about half-way towards a level population of between 8 and 12 billion people, barring a major catastrophe (Kates *et al.* 1990).

Rising human populations mean an inevitable expansion in human demands on the resources of the planet. Moreover, per capita demand for biotic resources has also increased, so that the increase in direct exploitation has been exponential rather than linear. The human species

Figure 11.4-1: Regional distribution of world population under the central scenario (Population Network Newsletter No. 23, 1993).

now appropriates some 40% of the net primary productivity of terrestrial systems (Vitousek *et al.* 1986), much of it as a result of food production (Brown 1994). Between 1950 and 1984, per capita grain production increased by 40%. Between 1950 and 1990, per capita supply of beef and mutton increased by 26%. In addition, world fish catches underwent a 4.6-fold increase between 1950 and 1989, doubling per capita production of seafood. World consumption of wood also increased 2.5-fold between 1950 and 1991, per capita consumption increasing by a third during this period (Durning 1994). As with food consumption, most of the growth in total and per capita wood consumption has occurred in the developing world.

Some indicators suggest that ecosystem and resource limits are already being reached. World fish harvests peaked at 100 million tonnes in 1989, and by 1993 had declined 7% from 1989 levels. Growth in grain production has slowed since 1984, with per capita output falling 11% by 1993. World economic growth has slowed from over 3% annually in the decade 1950–60 to just over 1% in the decade 1980–90 and less than 1% from 1990 to 1993. The Worldwatch Institute, extrapolating from historical data, forecasts that 'If current trends in resource use continue and if world population grows as projected, by 2010 per capita availability of rangeland will drop by 22% and the fish catch by 10%. The per capita area of irrigated land, which now yields about a third of the global food harvest, will drop by 12%. And cropland area and forestland per person will shrink by 21% and 30%, respectively' (Postel 1994).

The potential for further expansion of cropland area is thought to be small. Current figures show that roughly one-third of global land area is used in food production, 1.5 billion ha of this being used as arable land (Kendall and

Pimental 1994; Doos 1994). This current land area will decline as expanding global populations compete with agriculturalists for land for urban and industrial purposes and as land degradation takes its toll. The above authors, in agreement with WRI (1994), conclude that while there is a further potential for conversion of land to cropland (in the order of 1.5–1.7 billion ha) the areas with the best potential for cropland are already being used in this way; to realize any further expansion of arable land will involve the conversion of marginal areas such as tropical forests, steep hillsides and semi-arid regions which have relatively fragile resources – and a great deal of the world’s biodiversity. These areas are inherently unsuitable for crop production due to various physical and chemical soil constraints or unreliable rainfall.

Current trends in resource use and population growth are not, of course, perfect predictors of the future. Indeed, population growth is expected to level off by the end of the twenty-first century, and growth in food production has slowed in the last decade, with much of the remaining growth achieved by increasing output per area. Another disturbing trend, however, has been the rising concentration of income world-wide. From 1960 to 1989, the share of world income going to the poorest 20% of its population declined from 2.3% to 1.4%, while the share of income going to the richest 20% increased from 70.2% to 82.7% (United Nations Development Programme 1992). In other words, while per capita consumption is actually declining

in many parts of the developing world, 83% of world income is concentrated in the hands of ‘biosphere people’ whose disproportionate share of disposable income allows them access to increasing quantities of consumer goods.

11.4.2.2 *Changes in terrestrial and aquatic ecosystems*

Humans have already greatly modified the Earth’s surface. Ecosystems that have been substantially transformed, managed and utilized constitute about half the land surface of the ice-free Earth. Moreover, the rate of global land-use and land-cover change is accelerating. Conversion to cropland contributes to much of this land cover change; half of the area of cropland world-wide was added during the last 90 years, with croplands in the tropics doubling in area in the last 50 years. Rates of forest loss in the tropics are currently increasing by an estimated 4% to 9% annually (Houghton 1994).

Although land-use change outside the tropics is relatively limited, changes in characteristics other than area continue to occur, including loss of biomass and carbon storage (Houghton 1994; Ojima *et al.* 1994). Habitat disturbance and other anthropogenic factors may also contribute to species invasions or successful introductions of exotic species. The addition of species may have wide-ranging effects on community composition and dynamics, and alter productivity, soil structure, nutrient cycling and water chemistry (see discussion in Chapter 11.2).

Table 11.4-1: Total population size (in millions) in 12 world regions under the central scenario.

Region	Year					
	1990	2010	2030	2050	2070	2100
Northern Africa	140	226	332	440	529	595
Sub-Saharan Africa	502	924	1 499	2,097	2 561	2 700

Developing regions	4 149	6 097	8 167	9 859	10 897	10 980
Industrialized regions	1 142	1 255	1 333	1 378	1 437	1 582
World total	5 291	7 352	9 499	11 238	12 334	12 562

Biotic communities are also modified by the removal of animal and plant species (as noted in 11.2.3.4). The size of the this trade is staggering. At present, nearly 22 000 species are already threatened, including about 10% of all birds and mammals (McNeely *et al.* 1989); direct exploitation is one of the most important threats (WCED 1987). Although many areas of apparently natural vegetation remain, large animals on which many plant species are ecologically dependent may have been hunted out by humans (Redford 1992). The result may well be the eventual ecological collapse, or at least profound change, of these areas.

Not only will land areas continue to be affected, but so too will marine and freshwater areas. Marine ecosystems are increasingly affected by logging of forests and mangroves, siltation, dredging and channelization, pollution, shoreline development, oil and gas development and other human modifications, as well as introduction of exotic species and direct offtake of fisheries (Norse 1993). As L'vovich and White (1990 in Wolman 1993) have shown, human activities have also significantly altered the global distribution of runoff in rivers. They estimate an increase over a period of 300 years of about 20% in base flow and a decrease of 16% in surface runoff as a result of anthropogenic activities. More dramatic is a 300% predicted increase in consumptive use of water in irrigated agriculture over that of the last 300 years.

Habitat loss, modification and fragmentation are widely considered the most important causes of loss of biological diversity, with most current attempts to estimate and project the rate of species loss based on reductions in habitat area (WCMC 1992). Recent work (Tilman *et al.* 1995) has documented what the authors refer to as the 'extinction debt' associated with habitat destruction, in which the rate of extinction increases as a function of the area of habitat that has already been destroyed. For instance, destruction of an additional 1% of habitat causes the extinction of eight times more species if 90% versus 20% of a region has already been destroyed. Furthermore, an unanticipated effect of this habitat destruction may be the selective extinction of the best competitors – those species that are often the most efficient users of resources and major controllers of ecosystem functions. Thus, this extinction debt may have dramatic effects on the ecosystems of the future and the ability of these ecosystems to deliver vital services to human populations.

Human-induced change has shifted from the agricultural transformation of the surface of the Earth to industrial mobilization of materials and energy, to the current mix of agricultural, industrial and advanced-industrial transformation. As this range has expanded, so has the secondary interaction among the changes and hence the complexity of the problems that they pose for biological systems. The impacts of human-induced change are no

longer local or regional, but rather global, adding to the difficulty of assessing the human impacts on biodiversity and predicting the future.

Most global-scale impacts of human-induced change have been quite recent, particularly those dealing with biogeochemical cycles. For example, high-temperature industrial emissions alone now multiply the annual natural releases of arsenic by a factor of 3, of cadmium by 7, of mercury by 10 and of lead by 25 (Kates *et al.* 1990). Galloway *et al.* (1994) predict that by 2020, emissions of fixed nitrogen from fossil fuel and biomass burning are expected to increase over 1980 levels by 25% over North America, by more than half over the oceans of the Northern Hemisphere, and by at least 100% in the developing areas. Less than one-third of this increase is accounted for by population growth; the remainder will be achieved through greater per capita emissions, particularly in the developing world. These increases in nitrogen deposition have a number of effects, including fertilization of terrestrial and marine ecosystems, acidification, and increases in emissions of nitric oxide and nitrous oxide (see also Section 6).

Chameides *et al.* (1994) found that three regions of the northern mid-latitudes, which they termed 'the continental-scale metro-agro-plexus' currently dominate global industrial and agricultural productivity. Although they cover less than a quarter of the Earth's land surface, they account for most of the world's commercial energy consumption, fertilizer use, production of food crops and food exports. They also account for more than half the world's atmospheric nitrogen oxide emissions and, as a result, are prone to ground-level ozone pollution during the summer months. On the basis of a global simulation of atmospheric reactive nitrogen compounds, it is estimated that about 10% to 35% of the world's grain production may occur in parts of these regions where ozone pollution may reduce crop yields.

Exposure to yield-reducing ozone pollution may triple by 2025 if rising anthropogenic nitrogen oxide emissions are not abated. Although the current loss in crop yields from ozone pollution appears to be only a few per cent of the total loss, this may well change in the coming decades. Nitrogen oxide emissions predicted for 2025 not only intensify pollution but also enhance pollution in agricultural regions of the developing world. For 2025, they estimated that as much as 30% to 75% of the world's cereals may be grown in regions with ozone above the 50 – 70 ppbv threshold, which suggests that the agricultural losses may increase significantly. Further, this increased pollution effect will be occurring at a time when growing populations in developing countries will be straining food production capacities.

11.4.2.3 Climate change

The most complex manifestation of human-induced global change is that of the Earth's climate. The debate over the effects of ozone depletion and airborne particulates

(producing a cooling influence) and greenhouse gases (producing a warming influence) has produced a plethora of scientific material on the subject (summarized and assessed in Houghton *et al.* 1990). In an attempt to deal with the uncertainty in the prediction of the effects of climate change, IPCC has brought together a group of statements on various climate change issues which represents the degree of consensus on these issues (Table 11.4-2). Many climatologists believe that the ‘greenhouse effect’, caused by the observed accumulation of carbon dioxide, methane, nitrous oxide and chlorofluorocarbons in the atmosphere, is likely to raise mean world temperatures by about 2 °C by 2030 and mean sea levels by around 30–50 cm on a comparable time scale (Warrick *et al.* 1988). By the end of the next century, global average surface temperatures are predicted by the IPCC (1992) to increase by 2–6 °C with an attendant rise of sea level of 0.5–1.5 m. Such a change could be 10 to 50 times as fast as the natural average rate of temperature change since the end of the last glaciation (Schneider 1989). These changes could bring increased frequency and destructiveness of hurricanes (Emanuel 1987); more protracted droughts, longer and hotter heatwaves, and more severe rainy periods; and significant changes in the area of the great ice sheets of Antarctica (Frolich 1989).

Although the nature and causes of the greenhouse effect remain hotly contested (e.g. Bryson 1993), the scale and complexity of potential changes has led to a desperate scramble to foresee the future. Large-scale extinctions have

occurred in the past as a result of major climatic changes, cataclysmic disturbances and human activities (Crowley and North 1988; Gates 1993). Although there is little scientific consensus on the impacts of apparent current changes, it appears highly likely that global warming and associated disturbance events, particularly when coupled with human population growth and accelerating rates of resource use, will bring further losses in biological diversity (IUCN 1986; Gates 1993).

If predictions of a rapid temperature rise are realized, the effects of global change on patterns of human settlement, production and resource consumption will be dramatic. The effects of increased concentrations of atmospheric carbon dioxide and other greenhouse gases on climate will be particularly evident in northern latitudes. Rising temperatures are expected to bring about a poleward shift of cereal cropping in the major grain-producing – and exporting – areas of the Northern Hemisphere and an overall decline in grain production, and may reduce livestock production as a result of heat stress. Impacts on agriculture in the tropics are more difficult to anticipate because they are more vulnerable to the unknown effects of warming on the amount and distribution of precipitation. Agricultural pests and diseases may increase their geographic ranges, severity or both, as temperature and humidity rise (Parry and Jiachen 1991; Gates 1993).

Sea-level rise may also result in the loss of farmlands directly and through increased saltwater intrusion in coastal regions. For each centimetre rise in sea level, beaches may

Table 11.4-2: Degree of consensus on various climate change issues (WRI 1994).

Issue	Statement	Consensus
Basic characteristics	Fundamental physics of the greenhouse effect	Virtually certain
	Added greenhouse gases add heat	Virtually certain
	Greenhouse gases increasing because of human activity	Virtually certain
	Significant reduction of uncertainty will require a decade or more	Virtually certain
	Full recovery will require many centuries	Virtually certain
Projected effects by mid-21st century	Large stratospheric cooling	Virtually certain
	Global-mean surface precipitation increase	Very probable
	Reduction of sea ice	Very probable
	Arctic winter surface warming	Very probable
	Rise in global sea level	Very probable
	Local details of climate change	Uncertain
	Tropical storm increases	Uncertain
	Details of next 25 years	Uncertain

Virtually certain: nearly unanimous agreement among scientists and no credible alternative view.
Very probable: roughly a 9 out of 10 chance of occurring.
Probable: roughly a 2 out of 3 chance of occurring.
Uncertain: Hypothesized effect for which evidence is lacking.

erode a metre landward and storm surges, a major erosional force, will increase. For every 10 cm rise, saltwater wedges in estuaries and tidal rivers may advance a kilometre; and any sea-level rise will increase salinity intrusion into coastal freshwater aquifers (NAS 1987; Parry and Jiachen 1991). In addition, these changes will affect human settlements through changes in the availability of nearshore and brackish water organisms (Ray *et al.* 1992), important food sources for humans and other species.

Changes in cropping and crop location, livestock husbandry, irrigation, fertilizer use, pest control and soil management may enable human societies to maintain global levels of food production. However, it is likely that the frequency of both short-term and long-term crises in regional food supply will increase (Parry and Jiachen 1991). Moreover, the direct and indirect feedback effects (Ojima *et al.* 1994) of change of land use and technology on climate change are impossible to predict.

Major changes in global vegetation cover are also expected to occur in response to global climate change, primarily as a result of changing temperature and precipitation (Gates 1993). Schlesinger (1991), for example, predicts that rising temperature and precipitation will result in the expansion of boreal forests, but overall forest area is expected to contract, with grasslands and deserts increasing in extent. In North America, Europe, Asia and southern Africa, desert and other areas of sparse vegetation may expand at the expense of grasslands, shrublands and prairies. On the other hand, shrubby vegetation may spread into areas of sparse vegetative cover in southern Africa, Saudi Arabia and Australia (Woodward 1992).

More difficult to predict are the multiple interactions among changes in temperature and precipitation, soil quality and nutrients, and increase carbon dioxide. Although researchers know very little about the responses of vegetation to an increase in CO₂, laboratory studies increasing CO₂ concentrations have produced higher yielding wheat, larger sugar beets, and faster-growing radishes (Fajer *et al.* 1989). On the other hand, plants fertilized with CO₂ may be larger and grow faster but are less nutritious, so that insect pests must consume more to achieve their normal rate of growth and may pose a greater threat to crops and vegetation (Pain 1988a). Other observations suggest that plants respond to high CO₂ concentrations and may become more efficient in their use of water, thus contributing to the spread of shrubby vegetation into more barren regions of east and south Africa, Saudi Arabia and Australia (Fajer *et al.* 1989). In three sub-alpine conifers (*Pinus flexilis*, *P. longaeva*, *P. aristata*), greatly increased tree growth rates observed since the mid-nineteenth century exceed those expected from climate trends but are consistent in magnitude with global trends in CO₂ concentrations, especially in recent decades

(LaMarche *et al.* 1984). The IPCC (Schlesinger 1991) concludes that the growth effects of increased CO₂ will be greatly outweighed by the effects of temperature change, but few laboratory or field experiments have been conducted to evaluate such interactions.

A growing body of research has also examined the possible effects of climate change on individual species and biotic communities. This research suggests that biological communities will change and shift in complex and unpredictable ways as the geographical distributions of species are altered individually rather than in community units (Conner 1986). Further, because species are interrelated, any advantage falling to a given species in a closed system will affect other species in ways that are not always predictable. The rate of species invasions and extinctions is likely to accelerate further, bringing about complex changes in species compositions and interactions (Lodge 1993). Thus, rather than causing a simple northward or uphill shifting of ecosystems with all of their inhabitants intact, climate changes will serve to reorganize biological communities. For example, small changes in temperature alone may differentially alter the spacial distribution of predator and prey species in marine ecosystems (Murawski 1993). The 1982–3 El Niño event gave Galapagos increased rainfall by a factor of ten, with a resultant increase in seed production and caterpillar abundance. Ground finches responded to the increase in food supply by producing up to ten egg clutches instead of the usual one to five, increasing population size by a factor of four (Gibbs and Grant 1987). On the other hand, oceanic productivity was low, so that many seabirds did not breed. The Galapagos penguin and the flightless cormorant populations were reduced by 49% and 77%, respectively (Valle and Coulter 1987).

In forest ecosystems, rainfall and seasonality as well as temperature may be influential, particularly if they cause major changes in fruit or seed production. Further, the responses of forests to climate change may depend as much on the indirect effects of climate and vegetation on soil properties (Pastor and Post 1988). The ability of animal and plant species to shift their ranges in response to climate change also depend on dispersal mechanisms. Significant changes in temperature could occur during the life-time of some long-lived tree species; trees that disperse light, wind-blown seeds or drop seeds carried by animals may be able to disperse more than others (Peters 1992). On the other hand, tree species dependent on animals for pollination or seed dispersal may be affected by the changing ranges of animal species.

Peters and Lovejoy (1992) identify a number of mechanisms through which species and communities are likely to be affected as a result of the direct and indirect impacts of climate change. Populations located near the edge of a species' range, narrowly endemic species, and

endangered species that exist only in reserves or other extremely limited habitats, are especially vulnerable to global vegetation shifts. Species that are already threatened by direct exploitation and habitat loss and degradation are likely to be particularly susceptible to new threats. Coastal communities may be inundated as sea levels rise, while altitudinal shifts brought about by increased temperatures would reduce or even eliminate the ranges of montane and alpine species, many of which are already relictual, having been isolated by past climate changes. In hybrid zones such as those reviewed by Barton and Hewitt (1989), where genetically distinct populations meet, mate and produce hybrids, climate change may favour some species but cause the extirpation of others.

Because climate change is expected to be greatest at high latitudes, Arctic communities are also expected to undergo particularly rapid changes. Many of Europe's most productive wildlife habitats are in the far north, where algae, bacteria and other microscopic organisms grow on the undersides of sea ice during the spring. As the ice breaks up with the approach of summer, the organisms are released into the water, where they support a series of food webs that include large species such as whales, polar bears and seals. An increase of 5 °C over the next 50 years could melt even the permanent Arctic ice (Pain 1988a), bringing fundamental changes to polar ecosystems. Alexander (1992) notes that the melting of sea ice could also affect marine mammals that use ice floes for rest, travel and reproduction. If the ozone hole over the North Pole becomes firmly established, these impacts could be greatly magnified: El Sayed (1988) predicts that observed damage to the sensitivity of some plankton species by increased ultraviolet radiation would occur.

Severe temperature changes at northern latitudes may also have negative implications for species dependent on the timing of ice melt. Under normal conditions, snow and ice melt in Northern Europe over a period of several weeks, with the acidic meltwater draining through the soil, neutralizing it before it runs into lakes and rivers. An earlier and faster melt would cause the meltwater to run over the soil and into rivers, introducing a flood of acid water at a time when many animals are at their most vulnerable stage (e.g. eggs or fish fry). In addition, less water would be available in the following months, and with the warmer summer, water is likely to be in short supply. The pools and shallow lakes of the taiga and tundra – home to large populations of migratory water-birds – may become a far less productive habitat (Pain 1988).

Temperature change will also affect animal species directly. Dawson (1992) notes that animals that react to thermal stress by evaporating water may be negatively affected by rising temperatures and decreased water availability, while ectotherms are likely to experience extreme changes in metabolic and other bodily functions in

response to relatively small temperature changes. Rising ambient temperature may result in decreased fertility and fetal survival in mammals. Fish, reptiles and invertebrates that are subject to environmental sex determination may also be affected directly by rising temperatures. For example, higher temperatures produce more males of alligators and crocodiles and more females of some turtles, thereby enabling sex ratios to be adjusted in response to particular environmental conditions (Head *et al.* 1987).

Migratory species dependent on climate and prey availability throughout their migratory pathways are also acutely sensitive to the direct and indirect effects of global change (Pain 1988; Myers and Lester, 1992). In the Western Hemisphere, for instance, shore-birds such as sanderlings and plovers spend the winter in South America and travel north to breed in the Arctic in summer, stopping in Delaware Bay to feed on the eggs of horseshoe crabs that arrive and lay their eggs at the same time each year. If the timing of horseshoe crab egg-laying were to be disrupted, then the effects on the migrants could lead to a late arrival in the Arctic, missing the summer population explosion of the Arctic insects that is required to provide the hatchlings with sufficient food (Pain 1988).

11.4.2.4 Implications of global change

The role of change in ecological systems is increasingly recognized by natural scientists. The current paradigm, termed the 'flux of nature' or 'non-equilibrium paradigm', emphasizes process rather than end points, in contrast to the previous 'balance of nature' or the 'equilibrium' paradigm. The flux of nature acknowledges constant change, contending that natural communities have multiple stable states (Pickett *et al.* 1992). This approach is endorsed by plant ecologists such as Primack and Hall (1992), who concluded from their research in Asia that the forests they studied were characterized by unstable local populations of some common species and a rapid turnover of rare species. Condit *et al.* (1992) concluded that all biotic communities undergo constant flux as populations or individual species expand, contract, go extinct locally and re-migrate in response to endogenous ecological and evolutionary change and exogenous forcing.

Holling (1986) points out that the constant change occurs on an infinite number of spatial scales – from tree falls to the impacts of meteors, and temporal scales – from continental drift to sunrise and sunset. Variability and instability are indeed the traits necessary to retain the resilience of ecosystems, or their ability to adapt to disturbance through rapid shifts to alternate stable states or through evolutionary organizational change. An important implication of this view is that reductions in natural variability lead to fragility and lessen the likelihood that disturbance will bring about a transition to an alternate equilibrium.

Anthropogenic factors are of course among the exogenous forcing agents prompting change in ecological systems. Indeed, not only has the rate and scale of human-induced global change increased dramatically, but it is often acknowledged that human activity has modified the environment from a set of systems characterized by flexibility and constant flux, toward one that is more fragile and increasingly vulnerable to cataclysmic events. For example, tree species differ in their genetic variability, and those that have more variable populations might be able to respond with greater facility to changing climates (Davies and Zabinski 1992). Yet human-induced change through harvesting, habitat alteration or climate change tends to reduce the genetic diversity of individual species. Successful adaptation to climate change may also depend to a great extent on the ability of species to disperse to new areas, but this ability is increasingly impeded by human-induced landscape change (Peters 1992; Ryan 1992; Quinn and Karr 1993).

Human populations have already exerted fundamental influences on biological diversity and the Earth's capacity to support and maintain such diversity. It appears inevitable that changes already wrought will bring further losses of biodiversity in the future. However, changes are also integral to human populations, and in turn are often a response to shifts in biotic and abiotic systems. The following sub-chapter will assess current viewpoints on the ability of individuals, institutions and societies to evolve and adapt in response to the changes already under way in natural systems.

11.4.3 Human adaptations

Since the 1970s, an expanding body of literature has heightened awareness of the ecological impacts of economic development, and of their increasing severity. However, it is also increasingly recognized that environmental change is not only a consequence of affluence; it is also a cause and effect of poverty (WCED 1987). Malthusian forecasts indeed often present a scenario in which ecological collapse hits the poor first and hardest, causing famine and disease in developing countries on a scale surpassing anything yet experienced by the human species. In an era of global ecological and economic integration, the impacts of the crisis will be felt worldwide, inevitably affecting industrialized countries as well (Kaplan 1994).

Optimistic forecasts typically begin with a recognition that the needs of the developing world are tremendous, and those needs must be met, for humanitarian even more than for political reasons (MacNeill *et al.* 1991). It is therefore clear that continuing development will be necessary to meet the basic needs of present and future human populations (IUCN, WWF and UNEP 1980; WCED 1987). Optimistic scenarios envision several possible mechanisms

for averting global crisis, including continued technological development in response to growing population and resource constraints, sacrifice of future growth in consumption on the part of wealthy nations in order to allow future growth in the developing world (Goodland *et al.* 1991), and direct transfers of resources and technology to developing countries (Pearl 1989). Less clear is whether appropriate changes can and will be made in the policies and institutions that will determine patterns of growth and development.

11.4.3.1 The benefits of technology

Technological optimists often argue that even given recent evidence of the pace and scale of environmental change, human societies can continue to achieve quantitative and qualitative economic development through advances in science and technology. Technological optimism is typically linked to the economic arguments, for as Daly (1991) points out, in an era in which natural capital is the limiting factor to economic development, logic dictates that we maximize its supply and productivity. Environmental investment makes good economic sense; for example, Dogse and von Droste (1991) note that a US\$4.5 billion per year investment in soil protection world-wide would reduce annual agricultural losses by some US\$26 billion over a 20-year period. Furthermore, the world's shift from command to market economies offers greater opportunities for research and investment, since market economies are generally more open to change in response to signals of ecological distress (MacNeill *et al.* 1991; Ausubel 1993).

Technological innovation undoubtedly has the potential to stretch dramatically the limits of existing resources and systems in order to meet the needs of present and future human populations, and to alleviate many of the ecological and economic stresses caused by growing human populations and rising per capita resource consumption. Crop improvements and continuing developments in irrigation and pest control are likely to allow rising productivity as well as reducing known environmental impacts; for example, research is now under way to develop drought-resistant cassava and crops suitable for production on acidic soils (El-Sharkawy 1993; Rao *et al.* 1993). Continuing increases in food supply can also be maintained through increased aquacultural production as well as diversification of seafood consumption. Timber consumption can be reduced dramatically simply by further development of technologies to reduce waste or to mass-produce woodless paper (Postel 1994).

The effects of industrial emissions can also be reduced. For example, Goodland (1991) points out that the technology is available to reduce greatly the energy requirements of industry and other economic activity, so that carbon emissions can be reduced without necessarily implying a reduction in standards of living. To illustrate

this point, he notes that since 1973, Japan has increased its output by 81% without increasing energy use. Mills *et al.* (1991) conclude that even allowing for continued economic growth, by the year 2000 global greenhouse gas emissions can be reduced by 10% from current levels, at significant net economic benefit, through implementation of available energy-efficiency improvements. The impacts of ozone pollution on crop production can also be reduced by cutting the use of fossil fuels, limiting losses of nitrogen fertilizers from soils, implementing nitrogen oxide emission controls, and developing ozone-resistant crops. Enhanced networks for monitoring air quality throughout the world to assess the extent and severity of ozone pollution on continental scales will aid in evaluating the benefits of these mitigating strategies (Chameides *et al.* 1994).

As the rate and scale of global change has increased, so has the technological response. In the future, resource frontiers may expand beyond the Earth itself (e.g. Louis *et al.* 1993). In the shorter term, one of the most dramatic manifestations of technological response to resource limitations is biotechnology. Biotechnology, for example, offers the prospect of boosting crop yields with lower inputs of energy, water and pesticides. In the short term, potential advances include modification of food crops to increase resistance to insects, viruses and fungus; to improve processing quality or reduce spoilage; and to improve nutritional content. Fermentation and enzyme technology are already used in the manufacture of animal growth hormones to increase milk production or induce faster growth and production of leaner meat. In the long term, biotechnology may help to offset the impacts of global change on food supply, for example by producing staple crops that are resistant to drought, heat and other environmental stresses. New reproductive techniques for livestock, such as embryo transfer to stimulate production of multiple eggs for artificial insemination or cloning, could boost the reproductive rate of desirable species and reduce susceptibility to disease (Teale 1993; WRI 1994).

Biotechnology also offers the possibility of new production techniques that reduce emissions of chemicals and metals into the environment. Researchers have discovered that a completely biodegradable natural plastic is produced by some types of bacteria, which can be grown in large batches to harvest the plastic. Eventually, it may be possible to insert the genes into crop plants from which plastic could be harvested. Mass production of natural plastics could replace petroleum-based products in the market-place as well as easing problems of solid waste disposal (WRI 1994; Frederick and Egan 1994). Production of ethanol from waste materials, microbial coal desulphurization, and algae-fuelled combustion could reduce emissions to the atmosphere of chemicals contributing to acid rain and the greenhouse effect.

Biological elements are also used to detect organic

chemicals, pesticides and mercury in the environment, while bioremediation is increasingly used as a technology for cleaning polluted sites of metals and pesticides and treating acid drainage from coal mines. Biofilters are used to remove volatile organic compounds from industrial emissions, while bioleaching can lessen the environmental impacts of mining by enhancing recovery of minerals and reducing the release of metals into the environment (Frederick and Egan 1994).

It is becoming increasingly clear, however, that even rapid advances in productive and environmental remediation may not be sufficient. For example, increasing aquacultural output on the scale needed would require vast amounts of water and feed, and accelerate loss of coastal mangrove habitat (WCMC 1992; Brown 1994). Furthermore, the energy use and habitat modification associated with aquaculture also contribute to changes in the Earth's atmosphere and climate, which will in turn bring about dramatic changes in coastal ecosystems.

Biotechnology also brings its own set of problems and issues. In the past, human activities have resulted in biodiversity loss through the introduction of exotic species, a problem that could recur on a grander scale with the introduction of transgenic species. Altered organisms may out-compete other species in the environments in which they are released, or spread their altered genes by reproducing with native species (Pimental *et al.* 1989; Hoffman 1990; WRI 1994). Just as the Green Revolution was accompanied by hidden economic and environmental costs, it is possible that the Biotechnology Revolution will bring with it environmental consequences that have not yet been anticipated.

11.4.4 Constraints on human adaptations

11.4.4.1 Problems of uneven development

Technological solutions are also limited by their uneven availability. Not only is access to resources and skills unevenly distributed in the present, but the costs of new technology are likely to be prohibitive for many developing countries, so that future development will preserve the existing international economic structure for decades to come (Theys 1987). The first products of biotechnology research, for example, are just becoming available after 20 years of research, but research and development are concentrated in industrialized nations. Furthermore, much of the work in this area is directed toward high-value crops cultivated in developed nations, rather than the subsistence crops of tremendous importance to the developing world. Many of the products of biotechnology are likely to compete with tropical export commodities, further weakening the position of developing countries in international markets (WRI 1994).

The developed world is also much more likely to absorb successfully the economic costs associated with global climate change, and to have access to the benefits of biotechnology and other mitigative technologies that will allow the maintenance of high standards of living. Although there have been few attempts to date to compare human responses to climate change in developed and developing countries, Mooney *et al.* (1993) point out that high incomes in North America will facilitate mobility and adaptation in response to global change. By contrast, Fuentes and Muñoz (1993) hypothesize that climate change will force small-scale Chilean agriculturalists to intensify agricultural production on steep slopes and increase secondary activities such as logging and mining, thus intensifying the environmental impact of current land-use practices. Indeed, land-use and land-cover change are expected to outweigh the effects of climate change in South America. Low-income agricultural households in the developing world will be particularly vulnerable to the increasing frequency of extreme climatic events as well as temperature change, although forecasting of the effects on agricultural production has primarily been conducted in developed countries (Parry and Jiachen 1991).

11.4.4.2 *Prices, politics and alternative models of development*

Many observers argue that increasing supply from available resources, mitigating ecological damage associated with human activities, and developing adaptive technologies depend in large part on the ability to reform economic pricing and markets. Markets and prices must not only account for the environmental costs of production and consumption, but also compensate economic factors for the environmental benefits of resource conservation (McNeely 1988; Von Droste and Dogse 1991). Brenton (1994) considers that sustainable development will not emerge from 'dense webs of regulation' or the old command and control approach to environmental conservation, but only when conditions create more democracy, greater economic prosperity and a market that works for, rather than against, the interests of biodiversity. However, it is increasingly clear that the process of market reform and 'getting prices right' involves much more than simply freeing the market. Markets are the creation of human cultures, policies and institutions and are therefore subject to the many limitations of human understanding and politics.

The problem of scientific uncertainty is almost universal in the development of appropriate economic and environmental policy. According to Ludwig *et al.* (1993), the complexity and natural variability of biological and physical systems mean that levels of resource exploitation must be set by trial and error, with over-exploitation often not detectable until it is severe or even irreversible. Scientific consensus on the impacts of exploitation is

seldom achieved, even after the resource has collapsed. Furthermore, even when considerable scientific evidence exists that a given practice or technology will prove ecologically destructive, certainty has not proved sufficient to prevent the unsustainable use of resources. 'Resource problems are not really environmental problems: they are human problems that we have created at many times and in many places, under a variety of political, social and economic systems' (Ludwig *et al.* 1993: 549).

The development of appropriate economic and environmental policies to deal with biodiversity problems is thus hindered not only by problems of scientific certitude, but also by lack of understanding of the driving forces underlying individual and collective human behaviour and the relationships among human behaviour and global change. For example, only relatively recently has a body of evidence emerged on land-use and land-cover change that attempts to identify the social, economic and political forces that determine land-use patterns, and the understanding of relationships between land-use and global environmental change (Ojima *et al.* 1994). One of the contributions of this multidisciplinary research is the recognition that the fundamental causes of land-use and land-cover change may originate far from the ecosystem, or even region, affected. Regional and local responses to these causes vary widely depending on available resources and on local political, social and economic conditions, and further research is needed to determine local and regional variations in the human dynamics of global change (Kummer and Turner 1994; Skole *et al.* 1994; Collier *et al.* 1994).

One of the problems that this raises for appropriate environmental policy is 'scale mismatch', in which human responsibility does not match the spatial, temporal or functional scale of natural phenomena (Lee 1993). Adjustment of short-term, specialized human behaviours to account for their broader long-term ecological consequences depends in part on improved understanding of those consequences, but ultimately depends on politics (Holdgate 1991) – developing the institutions, management styles and policies that link individuals with their impacts on the global environment. Another growing body of research focuses on the development of diverse and context-specific institutional arrangements that correct such mismatches of scale and reduce the human conflicts they produce (Ostrom 1990; Bromley 1992; Haas *et al.* 1993).

11.4.4.3 *Building the capacity to adapt to change*

In the short term, policy-makers may be forced to respond to calls to limit human impacts on the Earth in ways suggested by the best available information and technology, even in the absence of consensus on human and natural systems. Given the scale of expected human-induced global change and the limitations of natural and

social science in predicting the future, some observers suggest that the major challenge in decades to come will be to adjust to the unexpected (Theys 1989). Planning methods for the uncertain and the unexpected involve adjusting the values for which ecosystems are managed, and adjusting the management styles adopted to achieve those values.

First, successful human adaptation to global change may depend on ecosystem management for the values of variability and resiliency, rather than for predictability, as has been the trend in the past. The maintenance of biological diversity is itself an important contributor to variability and resiliency, and many of the methods proposed for biodiversity conservation have important implications for global change. Walker (1989) suggests, for example, that conservation areas should maintain the elements of heterogeneity and variability that allow for change. Efforts to stabilize an ecosystem or to preserve an individual plant or animal species may be counterproductive, since ecosystem processes are the most critical value in conservation. Ryan (1992) applies this concept to intensively managed systems as well, noting that diversification of products and production methods within a management area also improves the capacity to adapt to change.

Second, several researchers have argued that planning for the uncertain and the unexpected can best be achieved by adopting a management style that is flexible, adaptive and experimental (Holling 1986). Holling argues that political decisions typically involve quick fixes for quick solutions, designed to maintain an imperfectly understood system in a constant state. The result is greater ecosystem fragility and higher stakes for future policy and management. The alternative of adaptive management is designed explicitly for decision-making in the face of uncertainty.

The principles of adaptive management may be described as follows: 'consider a variety of plausible hypotheses about the world; consider a variety of possible strategies; favour actions that are robust to uncertainties; hedge; favour actions that are informative; probe and experiment; monitor results; update assessments and modify policy accordingly; and favour actions that are reversible' (Ludwig *et al.* 1993: 549). Holling (1994) suggests a number of research strategies for experimentation in short-term change variables and monitoring of long-term shifts in ecosystem processes: experimentation and monitoring that combine perspectives from both the natural and social sciences may contribute greatly to our understanding of the human impact on global ecosystems.

Social and institutional learning is often an extremely slow process, and the scale and pace of changes in global biodiversity are increasing rapidly. However, the

possibility also exists for rapid change in human behaviour. For example, smokeless fuel regulations were adopted in response to killer smogs in London in the 1950s, and strong energy conservation measures were prompted by the oil crisis of the 1970s (Western 1989). More recently, abrupt shifts in management policies in response to ecological crises in a number of settings, from North America to the Baltic Sea, are also described by Gunderson *et al.* (1995; cited in Holling 1994). Thus while the unexpected may characterize the future, there are precedents for rapid leaps in the evolution of human capacity to modify human impacts on global ecosystems.

11.4.4.4 Uncertainty

The future is uncertain. We do not understand how little we know, nor what future citizens will value. H.G. Wells (1902), writing just before the Wright Brothers' first powered flight, was prescient regarding high-speed highways but could not imagine that airplanes might be important a dozen years later in World War I. Today we may be making similar errors in our valuation of ecosystems. Arguments for preservation of ecosystems such as rain forests include their use as a resource for medicinal chemicals, for preserving species, and for preserving indigenous cultures and knowledge systems. Additional arguments may emerge. For example, computer scientists are starting to explore adaptive, evolutionary, neo-biological designs based on close observations of ecosystems (Kelly 1994).

EXECUTIVE SUMMARY

The simplification of managed ecosystems in agriculture, forestry and aquaculture has provided humankind with important biological resources: foods and fibres. It has also had major effects on biodiversity. These effects are largely external to the market (they are not reflected in market prices) and so are ignored by resource users. The existence of external costs is said to be evidence of market failure.

The importance of the gap between the market price of environmental resources and their value to individuals and societies is only gradually coming to be understood. The causes of the gap are much better understood. One of these is ignorance or uncertainty about the social consequences of private actions. A second is a structure of rights that encourages people to ignore the known social consequences of their actions (the so-called ‘tragedy of the commons’ is an example of this). A third is government policy which not only fails to correct externalities, but makes the problem worse (through, for example, destumping subsidies in agriculture and forestry). This is evidence of policy failure. Together, market and policy failures are the main underlying causes of biodiversity loss.

To resolve the problems of market and policy failure we need first to evaluate their consequences. As the value that different individuals and different societies place on resources is measured by their willingness to forgo the benefits of alternative uses for the same resources, this requires the valuation of biological resources in alternative uses. Values vary with the preferences, culture, ethical values and world views of the people concerned, as well as the technology available to them. They also vary with the distribution of income and assets. Poor people are often willing to pay less for biodiversity conservation than rich people, not necessarily because they care less, but because they have fewer resources.

Valuation can be seen as a method of determining the relative importance of the environmental consequences of economic activities. It helps environmental authorities to make informed decisions about biodiversity conservation where there are alternative ways of treating resources. It helps, for example, to determine what development opportunities different societies need to give up if they wish to protect biological resources. Economists generally use one of two methods to estimate the value of non-marketed resources. They use either surrogate markets

to reveal the value people implicitly place on the resource, or simulated markets to get resource users to state their values explicitly.

The value of biological resources in use may be direct (they are used in consumption or production) or indirect (they support resources which have direct value). Biological resources also have non-use or passive use values stemming from the fact that we may care about others (or other species). Many domesticated biological resources are traded on markets, and their direct use values (such as crops, livestock and timber) are reflected in their market prices. Others derive value from their role in supporting marketed resources. A number of modern crop varieties and livestock strains, for example, contain genetic material incorporated through plant breeding from related wild or weedy species, or from more primitive genetic stocks. Biotechnology has increased the scope for gene transfer between unrelated species.

The use value of biodiversity is generally an indirect use value, and derives from the role of the mix of species in supporting either individual organisms (the value of habitat) or ecological services (the value of ecosystem functions). This includes ecological functions, protection functions, waste assimilation functions and wider functions such as microclimatic stabilization and carbon storage. Tropical forests, for example, provide not only the direct use values of timber, other forest products, medicinal plants, plant genetics, hunting and fishing, recreation and tourism: they also provide indirect use values of forests including habitat provision, soil conservation and soil productivity (through nutrient cycling), soil conservation and watershed protection with derivative services of water supply and storage, flood control, micro-climatic effects and carbon sequestration. These environmental functions all indirectly support economic activity and human welfare. The mix of species in an ecosystem enables that system both to provide the flow of ecosystem services and to maintain that flow over a range of environmental conditions. It has, in this sense, insurance value.

The current use of biological resources on the basis of market signals is both inefficient and inequitable. It leads to losses in social welfare that bear most heavily on the poorer members of this generation and will bear on all members of future generations. The appropriate policy

response is to develop institutions and incentives that will (a) confront resource users with the full social cost of their behaviour, and (b) enable those who invest in conservation to appropriate the benefits. Traditional approaches to protected areas have sometimes worked against the interests of local populations by removing traditional rights of access to, and benefits of, the resources in protected areas and by removing responsibility for management of the area from local people.

To be effective in an evolving ecological-economic

system, institutions need to be adaptive, i.e. able to respond to environmental feedbacks before those effects cause the system to break down. It may be necessary to bound economic activity to minimize the risk of irreversible damage to ecosystems on which human activity depends. But although preserving biodiversity through nature reserves and other protected areas may be an important short-term step where biological resources are under immediate threat, it is not feasible to protect critical ecological systems by excluding human users of wild resources.

12.1 Economic value and biodiversity

12.1.1 Introduction

Earlier sections of this Assessment have described what is currently known about the ecological importance of biodiversity. This Section considers what is currently known about its social importance: its 'value' to human society. The two things are not necessarily the same. That is, it does not follow that if biodiversity is important to the functioning of some ecological system it will automatically be valuable to society, or vice versa. The value of biodiversity to society depends on many things besides its ecological significance, and these things tend to vary from one country to another and one culture to another. Different societies place different values on biological resources, just as they do on other resources. Social preferences, technology, and the distribution of income and assets all influence perceptions of value. This section considers what lies behind the value placed on biodiversity by different societies.

The question is important because the value of biodiversity determines not just the sense of its 'worth' in any given society, but the way it is used or abused. The organisms that make up global biodiversity are part of the resources available to society, and their allocation between competing uses depends on their relative value. Whether the value of biological resources stems from their usefulness in production or consumption, from their cultural significance or from some notion of their right to exist, it will determine how much biodiversity is conserved. We need to understand the value of biodiversity if people are to understand both what is driving the present loss of biodiversity and what may be done to conserve it.

More particularly, the rationale for valuing environmental resources in general, and biodiversity in particular, lies in the perception that the signals generated by the market system – prices – are leading to excessive rates of biodiversity loss. Private resource users are encouraged to deplete biological resources even though it is against the interests of both local and global societies that they should do so. From an economic perspective, the allocation of biological resources on the basis of market signals is inefficient. It is also inequitable. Market allocation of biological resources has led to losses in collective well-being, and these losses are distributed in a way that is unjust from the perspective of both the poorer members of this generation and all members of future generations. Many environmentalists have reached the same conclusion. The advantage of an economic approach to the valuation of biological resources is that it provides a means of quantifying the error, and testing its sensitivity to assumptions made about the distribution of income and assets and the weight given to consumption by members of future generations. An economic approach also indicates how markets might be reformed to remove the current

sources of bias, and where it is not possible to reform markets, how governments might intervene to correct the signals to private resource users. It also indicates how and where economic activity may be constrained so as to protect biological resources that are important for maintaining the options open to future generations.

It is worth emphasizing this last observation. The problem of biodiversity conservation requires much more than just 'getting the prices right'. The allocation of property rights and the liberalization of markets are not panaceas. Both may improve the efficiency with which biological resources are allocated, but neither can ensure the alignment of private and social costs, and neither can protect the interests of either poorer members of this generation or all members of future generations.

The idea that the value of biological resources is a reflection of their social cost, the opportunities forgone by society by committing such resources in some way, is what makes the concept an economic one. The term 'value' clearly means different things to different people, and discussion about environmental values is often dominated by differences in the concept of value employed. Indeed, the debate over environmental values often turns on whether values are considered as ethical judgements or equivalence measures, i.e. whether environmental values are statements of principle or a reflection of social costs (Turner and Pearce 1993; Pearce 1994a). If we are interested in committing resources to biodiversity conservation, however, it is difficult to avoid the latter. It is neither possible nor sensible to conserve everything. Hence we have to ask, how much biodiversity should be conserved? Which species, habitats or ecosystems should be conserved first? How should conservation be linked to development?

Economic measures of value are not in fact blind to ethical judgements. The value accorded by society to biodiversity conservation may be driven by moral or ethical concerns. It may, for example, be driven by an altruistic interest in the welfare of other humans or other species. Moral or ethical concerns, like tastes and preferences, can be translated into a willingness to commit resources to conserve biodiversity. The process of valuation merely makes explicit something that is currently implicit. In some cases it does so by eliciting direct statements of preference. In others it does so by using actual behaviour to reveal preference. Societies which cannot or will not place a monetary value on human life, for example, nevertheless commit resources to health and safety which reveal their willingness to pay to save life. The implicit value of human life is said to be revealed by their behaviour. Similarly, societies which cannot or will not explicitly value biodiversity nevertheless make decisions involving the loss of diversity which reveal their willingness to accept compensation for that loss. Since different societies have

absence of some forum (market) in which to negotiate the value of those effects. Dependence on a common environment does not, of course, imply that all parties are affected equally by actions which generate externalities. Following Dasgupta (1991), it is useful to distinguish between two types of externality. Reciprocal externalities are those in which all parties using some resource impose external costs on all others. This is the classical problem of the commons. Unidirectional externalities are those in which the external costs or benefits of resource use are 'one way' (for example, upstream users of a resource can inflict damage on downstream users, but not vice versa). Both imply a structure of rights such that individual resource users are, in a sense, authorized to ignore the costs they impose on others.

There is a very wide range of rights currently conferred by law or custom on the users of biological resources, and these rights vary both from one country to another, and from one species to another. For example, rights with respect to migratory or otherwise mobile organisms typically differ from those with respect to stationary organisms. People very often 'own' land or its vegetational cover, but seldom 'own' migratory species which may cross their land. If the rights that people have allow them to ignore the consequences of their own actions on others, the private cost of the use of biological resources will differ from the social cost (private value will differ from social value), and resources will be misallocated. Rational individuals faced with prices that do not reflect the social cost of resources will make decisions that may be both inefficient and unfair from the point of view of society.

Other factors behind the divergence of private and social costs of biotic resources are those that make existing markets ineffective. This includes ignorance, uncertainty, the distribution of income and assets, the strategic market behaviour of economic agents and, most importantly, the way in which governments intervene in those markets. It is argued, for example, that the system of administered prices in many agricultural markets has at once distorted the private cost of biological resources and, in the case of the less developed economies at least, has reduced rural incomes (Pearce *et al.* 1988; McNeely 1988). Destumping subsidies in agriculture and stumpage fees or royalties in forestry, for example, are argued to have encouraged deforestation at excessive rates, both in terms of rates of felling in timber concessions and in the clearance of ever more marginal land for agricultural purposes (Warford 1987; Repetto 1989; Barbier *et al.* 1991). Subsidies designed to promote cash cropping as a means of increasing export revenue are argued to have resulted in leaching, soil acidification, and loss of soil nutrients, and to the reduction in the resilience of key ecosystems (Grainger 1990). Where pricing or other policies fail to close the gap

between private and social value, economists tend to refer to policy failure. Together, market failure and policy failure are the main underlying causes of biodiversity loss.

There is still a great deal to be done to establish where the biases in the set of prices confronting resource users lie. The implicit subsidy on agricultural land offered by traditional (common or communal) land tenure systems may, in many cases, be a more important source of bias than the price of agricultural outputs or non-land inputs (Githinji and Perrings 1993; though see Berkes *et al.* 1994 for counter-examples). In all cases, however, the main effect of a bias in the private cost of biological resources is that users do not accord them the weight they should. This is, of course, exactly the point made by environmentalists. The purpose of a valuation exercise is to establish what the weight should be if the interests of the whole of society are taken into account.

12.1.3 Poverty, discounting and value

Part of the problem in evaluating external effects is to determine the weight given to any future costs and benefits of resource use. This involves the question of how future costs and benefits should be discounted. The notion of discounting is quite intuitive. That is, most people have a reasonable intuition about the value they would place on something delivered in a year's time compared to its value delivered today, and so a reasonable intuition about how they would discount the future. The problem here is that discounting has ethical implications. Discounting implies that the welfare of future generations counts less than the welfare of the present generation. In fact, the ethics and rationality of discounting future costs and benefits are two of the most debated areas in economics (see Goodin 1982; Hanley and Spash 1994 for some of the points at issue). Moreover, given the enormous implications of the rate of discount in the use made of environmental resources, it is not at all surprising that these debates have continued longer in environmental economics than elsewhere. It is, moreover, easy to see where the moral qualms induced by discounting come from. The higher the rate of discount the greater, in general, is the rate at which natural resources, including species, are optimally depleted. The higher the rate of discount, the less interesting are the costs of present activities visited on future generations. The higher the rate of discount, the more uncertainty is screened out of the information relevant to the decision-making process.

It is not always the case that higher interest rates (the relevant discount rate for most investment projects) imply higher rates of depletion of renewable environmental resources. By depressing demand for investment funds, high interest rates can reduce the rate of exploitation of renewable resources (Pearce *et al.* 1990; Rowthorn and Brown 1994). Nevertheless, the iron law of the discount rate – by which species with a growth rate less than the rate

of discount will be optimally driven to extinction unless the growth in the value of the species compensates for the difference, or their extraction is regulated – has brought more opprobrium on economists than almost any other proposition in economics.

Despite this, the arguments of the 1970s against discounting on the grounds that it induces individuals to inflict harm on future generations (Randers and Meadows 1973; Myrdal 1975) have fewer and fewer echoes in recent work, and those who still hold to the view (e.g. Daly and Cobb 1989) acknowledge that a low discount rate is not sufficient to prevent harm being inflicted on future generations. It is now widely recognized that discount rates equal to the marginal productivity of the asset base may be ethically ‘neutral’. Indeed, even those most concerned about the intergenerational equity implications of current environmental practices, argue that equity should be satisfied through intergenerational transfers, and not through the discount rate (Norgaard and Howarth 1991; Norgaard 1991).

Whatever method is used to uncover the private value of biological resources, this will be the same as the social value only if there are no externalities, if there is perfect information, if there are no biases in the formation of expectations, and if all future costs and benefits are discounted at the social rate. Since there is no reason to believe that these conditions will hold in even the simplest case, there is also no reason to believe that the private valuation of ecological services is an adequate approximation of the social value of those services.

Both information about future effects and the rate at which they are discounted turn out to be sensitive to the level of market income. Information is not costless. The poor may understand the value to them of using biological resources in familiar ways, but may not understand the value of the same resources to society under different technologies. The poor, by definition, are able to command less information than the rich. In addition, there is a strong relationship between income and the rate at which people discount the future. Because what matters is consumption today, people in poverty tend to discount the future costs of resource use at a very high rate, so distorting the private value they place on future effects (Perrings 1989a). For similar reasons, poverty turns out to be positively correlated with high rates of population growth, or at least with high rates of fertility – with all that this implies for pressure on environmental resources (Dasgupta 1993).

In addition, poverty turns out to be closely related to the same market and policy failures that lie behind the gap between private and social value. There is considerable evidence that a major source of poverty amongst the users of natural resources in many of the least resilient ecosystems has been due to manipulation of the set of prices they face. In some cases, such manipulation reflects

government intervention. It has, for example, been observed that a major effect of price intervention in agricultural markets in the less developed economies has been the reduction of producer incomes (cf. Warford 1987). In other cases – those which interested Sen (1981) in his work on poverty and famines, for example – such manipulation has reflected the strategic behaviour of producers in free markets. Both have had the same effect. In meeting their immediate consumption needs, the poor have been compelled to ignore the potential future consequences of the use they have made of environmental resources. It has been privately rational for them to ignore the future damage they do to both habitats and species.

An additional ‘cause’ of poverty is the distribution of assets, whether marketed or non-marketed. It is well understood that those with ‘uneconomic’ holdings of land and other natural resources, and who have no other source of income, will tend to over-exploit those holdings. It is of some concern, therefore, that there has been a marked and continuing tendency for the distribution of both assets and income to widen over time in many of the low income countries, reflecting both the erosion of traditional rights of access to the resource base and increasing human population pressure (see Ghai and Radwan (1983) for an example from sub-Saharan Africa). It turns out that gender is an important factor in this trend. Female-headed households typically have access to a much smaller asset base than male-headed households, and it is not coincidental that relative poverty in the sense of relative deprivation is reckoned to bear most heavily on women (UNDP 1990). In addition, the lower the security of tenure attaching to the use of an asset, the higher tends to be the rate at which the future costs of resource use are discounted: i.e. the lower the incentive to manage it on a sustainable basis.

12.1.4 The value of diversity

Later chapters in this Section distinguish clearly between direct and indirect values. Direct values stem from the direct consumption of resources. Indirect values stem from the fact that some resources, though not directly consumed, are nevertheless necessary to the production of resources that are directly consumed. Indirect effects are much more likely to be external to the market than direct effects. Biodiversity, because its value is indirect, tends to fall into this category. Where the value of particular organisms often stems from their use in consumption or production, or their ‘totemic value’, the value of the mix of organisms lies in its role in supporting the productivity of the system from which individuals are extracted. To see the origin of this value, however, we recap the role of biodiversity in ecosystems discussed in detail in Sections 5 and 6.

Although any ecosystem contains hundreds to thousands of species interacting amongst themselves and with their

physical environment, the emerging consensus is that the system is driven by a small number of biotic and abiotic variables on whose interactions the balance of species are, in a sense, carried along (Holling 1992). This has led to the characterization of species as either 'drivers' or 'passengers', with some species becoming 'drivers' only occasionally and under particular conditions that trigger their key structuring function. There is certainly empirical evidence that the deletion of some species appears to have minimal effect on the functioning of ecosystems, whilst the deletion of others triggers a fundamental transformation from one ecosystem type to another, e.g. from forest to grassland, or grassland to a shrubby semi-desert (Walker *et al.* 1969; Holling 1973). There are, however, insufficient long-term studies to show whether the presence or absence of rare species may cause slower, more subtle shifts in ecosystem structure or function.

The fundamental point is that only a small set of structuring processes made up of biotic and physical processes are critical in forming the structure and overall behaviour of ecosystems, each of which dominates over a definable range of scales in space and time. These processes are supported by groups of species, each of which includes several species of plants or animals having complementary functions with respect to the processes concerned. Examples include the set of grass species that maintain the productivity and resilience of savannahs (Walker *et al.* 1969), or the set of insectivorous birds that mediate budworm outbreak dynamics in the eastern boreal forest (Holling 1988). Indeed, there is growing evidence that the great complexity and diversity within many ecosystems can be traced to a small number of critical structuring processes mediated either by individual 'keystone' species (Paine 1966) or by sets of species (Holling *et al.* 1995).

The implication of this is that the resilience of ecosystems depends on the range of species capable of supporting the critical structuring processes of those systems under different environmental conditions – conditions that subject the system to different degrees of stress and different magnitudes of shock. Some individual species and some sets of species have greater ecological value under the current state of nature than others, but this does not imply that all other species are redundant (in excess supply) and hence of no value. The importance of the mix or diversity of species for the resilience of ecosystems lies precisely in the fact that species which are passengers under one state of nature may have a key structuring role to play under other states of nature.

A change in the composition of species that affects any one of the key structuring processes may have profound consequences for the ability of an ecosystem to provide economically valued ecological services. The ecological impact of biodiversity loss is conditional on the link

between the species and the critical processes of the ecosystem concerned. Whether the deletion of some species does affect such processes is a function of the number of alternative species that can 'take over' a particular function when an ecosystem is perturbed (Schindler 1988, 1990b). Evidence from aquatic ecosystems suggests that the most sensitive components of food webs, energy flows and biogeochemical cycles are those where the number of species carrying out that function is very small (Schindler 1990a).

These remarks are more relevant for terrestrial systems or for aquatic systems dominated by substrate (nearshore ecosystems with abundant recruitment, coral reefs or shallow freshwater lakes) than for open pelagic marine systems. The latter have different physical properties of land and air on the one hand, and water on the other. A hierarchy of structures, similar to that in forests, occurs in the oceans. These structures are produced by physical forces and result in a nested set of levels that increase in scale from turbulence, to waves, to eddies, to gyres. As in a forest, animals respond by adapting to the structure of those levels – for example, phytoplankton to fine scales, predatory fish to coarse. In oceans, however, pelagic organisms cannot control the structure of marine systems (Steele 1985, 1989). The physical properties of water and absence of fixed substrate leave no alternative except for pelagic organisms to adapt to variability imposed by physical processes.

12.1.5 Biodiversity and ecosystem functions

All concepts of diversity imply some measure of distance between the elements of a set (Weitzman 1995), but the particular measure of distance judged to be relevant depends on the significance of diversity. Some estimates of the 'ecological' value of biodiversity, for example, assume that the relative value of each species depends directly on the phylogenetic distance between species (Vane-Wright *et al.* 1991). The focus on the complementarity between the functions of species supporting critical structuring processes, over a range of environmental conditions, implies that the relevant concept of diversity is functional diversity.

While functional diversity implies a particular measure of distance between species, it is more difficult to identify and classify than other categories of diversity. This is partly because functional diversity can refer to two rather different concepts: the diversity of the ecological functions performed by different species, and the diversity of species performing a given ecological function. By the first concept it is a measure of the number of species required for a given process. By the second concept, it is a measure of the number of species supporting the structuring set of processes under different environmental conditions (Schindler 1990a). Where the issue is the relation between

Box 12.1-1: The value of the loss of functional diversity.

A major problem confronting livestock owners is the large inter-annual variation in fodder production in response to variation in rainfall. This may vary five-fold or more from one year to the next (Barnes 1979). In these circumstances economic decisions with respect to stocking and offtake levels have resulted in a significant change in the functional diversity and hence the resilience of many rangelands.

Specifically, grazing patterns have led to two major changes in the diversity of the range. The first is well documented and well understood. It involves the loss of perennial grasses and their replacement by annuals, which vary far more in response to fluctuations in rainfall. The second involves the disruption of a more subtle ecological mechanism to counteract inter-annual variation in production: a high phenological diversity in the grass sward. In systems not subject to grazing pressure there tend to be approximately even amounts of early-, mid- and late-season grasses. This means that there is about the same amount of grass able to respond to rainfall whenever it occurs in the season (Walker 1988). However, in systems subject to heavy grazing pressure, the loss of early-season palatable species means an increase in the relative amount of later-growing species (Silva 1987). Where this occurs the loss in phenological diversity means that in years of mostly early-season rains, production will be less than expected even though there may still be roughly the same amount of grass cover. The grass sward still appears to be healthy, and the average biomass is much the same. But because the functional diversity of the range has been reduced, the inter-annual variation in fodder production tends to be greatly exaggerated.

As an illustration, McNaughton (1985) has shown that in the Serengeti grasslands those communities which vary least in year-to-year production show relatively greater changes in species contribution to biomass. In other words, communities exhibiting varying species responses to a fluctuating environment tend to be most constant in terms of primary production. The same set of species are present all the time, but different species contribute to biomass at different rates depending on environmental conditions. Assuming, for purposes of illustration, that the only output of interest is the liveweight gains of stock grazing the range, the economic value of the change in diversity is readily determined from the change in liveweight gains associated with the reduction in average biomass caused by the loss of grass species.

diversity and ecosystem resilience it is the second concept that is important. But where we seek the value of functional diversity in general, it is intuitive that both things are important: the complementarity between species supporting the critical structuring processes of a system under given environmental conditions, and the range of species capable of supporting the same processes under different environmental conditions.

One of the difficulties in measuring functional diversity in the second sense is that the range of species capable of performing particular functions under different environmental conditions is not readily observable. Nevertheless, for many important cases, the value of the loss of functional diversity may be obtained by indirect methods. Box 12.1-1 illustrates this for the example of semi-arid rangelands. In general, the value of the functional diversity of species depends on the value of all of the ecological services provided by those species and the degree of complementarity between them in the provision of those services. This value depends on the range of environmental conditions over which the system may have to operate.

12.1.6 Concluding remarks

Section 12 is divided into two parts. The first part, comprising Chapters 12.2 to 12.4, discusses the methods by which economists are currently trying to uncover those

values indicated in Figure 12.1-1 that are not captured in market prices. These chapters review the state of the art on the valuation of both individual biological resources and the mix of resources in particular ecosystems and habitats. The second part, comprising Chapters 12.5 to 12.7, discusses current estimates of the value of biodiversity using these methods and draws out some of the policy implications of the section. Although the focus of the Section is on valuation and estimates of value, it is important to underline the point that valuation is interesting only as an adjunct to policy. It is important to understand the value of individual resources and the mix of resources if we are to understand how much biodiversity should be conserved. But there is no merit in valuation for its own sake.

The main points to be kept in mind in reading these chapters are the following.

- The **proximate causes** of excessive biodiversity loss are to be found in harvesting, land conversion, and pollution activities. The **underlying causes** are to be found in the incentives to individual users of biological resources to ignore the effects of their behaviour on the rest of society, i.e. the **private** and **social** value of resource use differ.
- The **private value** of a biological resource in some use is the value of the opportunities forgone by the user:

its **private opportunity cost**. The **social value** of the same resource, its **social opportunity cost**, is the value of the opportunities forgone by society as a whole.

- The value that individuals and societies place on the conservation of biodiversity is measured by their willingness to forgo the benefits of alternative uses for the same resources. This is reflected in one of two measures: a measure of their **willingness to pay** to acquire a benefit or satisfy some rule or code of behaviour, or their **willingness to accept** compensation for the loss of a benefit.
- Willingness to pay or willingness to accept compensation vary with the **preferences, culture, ethical values** and **world views** as well as the **technology** available to individuals and societies.
- Willingness to pay or willingness to accept compensation is also highly sensitive to **income**. Poor people are willing to pay less for biodiversity conservation than rich people, not because they necessarily care less, but because they have fewer resources. Poor people are also less able to command the information needed to understand the long-term benefits of conservation, and to accept the short-term sacrifices needed to realize those benefits. They have fewer options.

12.2 Use and non-use value

12.2.1 A typology of values

The preceding chapter observed that biological resources and the diversity of those resources have both use and non-use value. This chapter reviews what is currently understood about each type of value. In the treatment of use value a distinction is drawn between the value of the mix of species in (a) supporting one or more organisms (the value of habitat) and (b) supporting the provision of the economically interesting range of ecological services (the value of ecosystem functions). Use values include, as we have seen, both direct and indirect values. Direct use values are the values derived from direct use or interaction with a biological resource or resource system. In contrast, the indirect or derived value of biological resources and ecological systems stems not from direct interaction or use but from the role of these resources and systems in supporting or protecting economic activity. The main objective of attempts to estimate the use value of habitats and ecological systems is, in fact, their indirect value.

The concept of indirect value implies that even though some organisms have no immediate use in consumption they may be necessary to the production of organisms that do have an immediate use. For example, forest litter

invertebrates may not be used themselves, but may be essential to the regeneration of forests from which timber is extracted. Trees and forest litter invertebrates, in this example, would be said to be complementary inputs in the production of timber. As inputs, both derive value from the value of timber produced. The value of trees is direct. They are the immediate source of timber. The value of the litter invertebrates is indirect. Their various functions contribute to the growth of trees. Hence, whether the end users of timber recognize the value of litter invertebrates or not (whether they are priced in the market or not), any actions that interfere in the functions performed by litter invertebrates will involve costs in terms of timber forgone.

The typology described in Chapter 12.1 (Figure 12.1-1) distinguishes between two types of use value and two types of non-use or passive use value in nature. Neither form of use value is in itself controversial, but a substantial debate has been in progress for some time over the meaning and significance of non-use or passive use value in nature. Some environmental philosophers (biocentrists) have interpreted this value as ‘inherent worth’: an intrinsic value that is completely separate from the human–environment valuation relationship. According to this position non-human biota, and perhaps even non-sentient things, have moral interests or rights to existence (Turner *et al.* 1994; Turner and Pearce 1993). An extreme version of bioethics would make environmental rights absolute and therefore not open to trade-offs on the basis of a ‘deep ecology’ meta-ethical principle. Use values, on the other hand, are relative and linked to individuals and their preferences or needs. Hence, if more biodiversity conservation is chosen the opportunity to satisfy other preferences or needs is foreclosed. So all resource allocation policy decisions incur opportunity costs (i.e. forgone alternatives). Thus the use value of biodiversity is not absolute, it is relative and as such can be balanced (in a cost–benefit assessment) against other ‘good’ things or ‘worthy’ causes that individuals may want to use or support.

An important point in this context is therefore whether individuals treat environmental services as ‘commensurable’ with ordinary produced goods and services. Sagoff (1988), for example, claims that they do not, and argues that social decision-making should not be based on commensurability (see also Blamey and Common 1994). A majority of environmental economists would argue that such commensurability does exist, as long as the overall life-support regulatory functions of the environment are not threatened.

It is not, however, necessary to ascribe absolute value to environmental conservation/preservation in order to provide more safeguards against biodiversity loss than currently exist. Such extra safeguards could be justified in terms of ‘Q-altruism’ motivations (Randall 1991; Randall

and Stoll 1983). Here, moral principles recognizing the 'interests' of non-human species and their supporting habitats could be used to buttress a case for extra, but not unlimited, sacrifices incurred to better safeguard biodiversity. The values expressed are still anthropocentric but relate to the perceived interests of other species. Bequest motivations underpinned by an inter-generational equity concern would add further support to biodiversity conservation enhancement.

The largely philosophical debate over the need for and composition of an adequate environmental ethic has become rather sterile. This is the case because the discussion has focused on use value versus non-anthropocentric intrinsic value in nature, i.e. relative versus absolute valuations. In the real world of pragmatic policy-making the instrumental–intrinsic distinction is usefully maintained only if it is interpreted solely in an anthropocentric (human centred) way. Thus a case for biodiversity conservation should be supported not only on the grounds of the significant amount of human use value that is at stake, but also because this allows society to set things aside (Pearce *et al.* 1990; Turner 1993) and exempt them from use. According to Hargrove (1992) this would reflect 'our desire as individuals, as a society, and as a historically evolved culture to value some things non-instrumentally and to set them aside and protect them from exploitation'. The question then becomes what 'things' should be set aside and should this be at any cost?

The motivations behind non-use or passive use value are some combination of: individuals; perceived benefits; altruism towards friends, relatives or others who may be users (vicarious use value); altruism towards future generations of users (bequest value); and altruism toward non-human nature in general (existence value). But several questions remain to be answered, including what precisely is meant by altruistic motives and behaviour and which values involve use of the resource and which do not. We do not yet have anything like a full picture of the mutually exclusive set of motivations underlying individual preferences for environmental goods.

All altruistic motivations involve improvements in an individual's welfare. According to Kahneman and Knetsch (1992a) altruism is thus no more than the purchase of moral satisfaction, a 'warm glow effect', and is a self-regarding motivation. On the other hand, existence value has been argued to involve a moral 'commitment' (Sen 1977) which is not in any way all self-interested. Commitment can be defined in terms of a person choosing an act that he or she believes will yield a lower level of personal welfare to him/her than an alternative that is also available. The person does not directly desire to reduce their own welfare, but that adherence to one's moral commitments will be as important as personal economic welfare maximization and may conflict with it. Thus the human valuer recognizes an

intrinsic 'moral resource' value in non-human nature and is prepared to give up scarce resources to conserve such nature, even though no use or *in situ* contact is contemplated. They are also unlikely to accept compensation for the loss of environmental resources, especially if the resources have the characteristics of uniqueness and non-substitutability. According to Sagoff (1988) this is because individuals are here acting as citizens and not consumers. Clearly there are difficult theoretical and philosophical issues so far left unresolved in the non-use valuation debate. The citizen/consumer dichotomy, for example, is far from clear cut, and operating in citizen mode does not have to preclude recognition of the economic costs and benefits involved. The results of empirical studies of the existence value of a range of biological resources (reported in Chapter 12.5) indicate just how wide a variation in response has been observed, and this reflects on at least some of these issues.

12.2.2 Value, ethics and equity

The costs of biodiversity loss and consequent ecological degradation are not distributed equally. Biodiversity loss raises issues of both intra-generational and inter-generational equity. The poorest individuals and societies often face the largest relative losses from biodiversity loss and ecosystem degradation. Many low- and lower-middle income developing countries are very dependent on natural resources (both in their domestic economic activities and in their export trade) (Barbier 1994a). For most low-income economies a sustainable development path requires careful management of the natural resource base so that 'natural' capital is not over-depreciated and future economic progress inhibited. A further worrying trend in developing economies is the concentration of the poorest groups in 'ecologically fragile' zones – areas where environmental damage threatens economic welfare (Barbier *et al.* 1994). This means that the poorest income groups tend to be at the greatest risk from the effects of biodiversity loss. Because the underpinning ecosystems in these areas are relatively less resilient, the problems of threshold effects, ecosystem collapse and scarce resources may be particularly severe for these poor households.

Similarly, any change in biodiversity that affects ecological functioning and resilience has implications for future generations (an inter-generational equity concern). The conversion and modification of ecosystems by the current generation may mean that 'less' biodiversity is available for future generations. The current generation may be making future generations unavoidably worse off by reducing the opportunities available to them. This may increase the cost of maintaining ecosystem functions.

The Brundtland Report argued that, 'Humanity has the ability to make developments sustainable – to ensure that it meets the needs of the present without compromising the

ability of future generations to meet their own needs' (WCED 1987). By this criterion, where biodiversity loss is unavoidable, future generations should be compensated for any costs they incur. The mechanism by which the current generation can ensure that the future is compensated, and is not therefore worse off, is the transfer of capital (including natural biodiversity). To anticipate the conclusions of the section, it is worth noting that the inter-generational equity goal can be achieved by strategies aimed at fostering an efficient, diversified and ecologically sustainable economy; by maintaining natural capital stocks, and in particular 'critical' natural capital that is non-substitutable and therefore the loss of which is irreversible (i.e. a 'constant capital' rule); by adopting safe minimum standards and the precautionary principle which suggests 'risk averse' behaviour in the face of uncertainty and lack of full scientific knowledge; and finally by adopting policies that enhance ecological, social and economic diversity so that the next generation is left with an equivalent resource endowment (allowing for some trading between different forms of capital) and opportunities for social and economic activity (Young 1992, 1993).

The ethical argument at the core of the inter-generational equity proposition is that future generations have a right to expect an inheritance (capital bequest) sufficient to allow them the capacity to generate for themselves a level of well-being no less than that enjoyed by the current generation. The requirement is therefore for an inter-generational social contract that guarantees the future the same 'opportunities' that were open to the past. Philosophers have put forward two ethical positions which can be seen as supportive of the constant natural capital rule (although they would also buttress a constant capital rule given smooth substitution between the different forms of capital). The first is known as the 'Lockean Standard' view, after the philosopher John Locke. This lays down that each generation should leave 'enough and as good for others'. A more modern view, known as the 'justice as opportunity' view, holds that the present generation does not have a right to deplete the economic and other opportunities afforded by the resource base. Since the resource base cannot literally be passed on 'intact', what is proposed is that future generations are owed compensation for any reduction (caused by the current generation) in their access to easily extracted and conveniently located natural resources. If justice is to prevail, the future's loss of productive potential must be compensated for (Page 1992; Pasek 1993).

Bequest value may be particularly significant for populations local to an ecosystem or natural environment who currently enjoy many of its benefits. Such individuals tend to want to see their way of life or intimate association with the ecosystem ('a sense of place') passed on to their heirs and future generations in general.

Bequest motives have not been seen as 'core values' in the conventional economic model. Nevertheless, a minority of economists have long suggested that the self-interested model of human behaviour is too simplistic (e.g. Harsanyi 1955; Sen 1977). Various forms of self-serving and social altruism have also been modelled by economists (Collard 1978; Margolis 1982; Sugden 1984; Andreoni 1990) and must in some sense be necessary for existence value to be present. Charity contributions and voluntary work are also evidence that self-interest and free riding need not be the only human traits. It also seems likely that peer group and local community 'pressures' influence charitable behaviour within the constraints of prices and individual income levels. Andreoni's (1990) analysis of charitable donations as private benefits and the 'warm inner glow' effect has been used by Kahneman and Knetsch (1992a, b) to suggest that these contributions are a substitute source for the services linked to the non-use environmental values. But Smith (1993) has countered that if people have 'warm glow' and altruistic motives for charity-giving, all that means is that charity is a mixed public/private good.

Bequest motivation and value related to biodiversity conservation fit neatly into the 'justice as opportunity' view. The basic argument is 'contractarian' in philosophical terms. The philosopher John Rawls has used contractarian philosophy in order to formulate principles of justice chosen by rational and risk-averse individual representatives from contemporary society in an 'original position' (the negotiations) and generating from behind what he calls a 'veil of ignorance' (i.e. individuals are assumed not to know to which stratum of society they themselves belong). The contractarian approach is therefore based on actual or hypothetical negotiations that are said to be capable of yielding mutually agreeable principles of conduct, which are also binding upon all parties. One of the principles that Rawls derives is known as the 'difference principle' or maximin criterion. What it boils down to is the guarantee of an acceptable standard of living for the least well off in contemporary society (Rawls 1972). Other writers have since sought to place the maximin criterion in an inter-generational context (Page 1983; Norton 1989). In this context the rule becomes one of passing on over time an 'intact' resource base. The constant capital assets rule, or the constant natural capital assets rule, would therefore be relevant to this inter-generational equity case (Pearce *et al.* 1991, Ch. 11).

12.2.3 Social and cultural differences in the perception of value

It should be noted that both sides of the ethical debates over bequest and existence values are grounded in a particular world view that has emerged but recently in human history – i.e. some 6000 years ago with the establishment of towns in fertile river valleys under settled

cultivation (Lenski and Lenski 1978). In what follows we indicate how this view differs from others that have existed in the past and that still exist in some societies. This world view is characteristic of large-scale societies, heavily dependent on resources brought from considerable distances. It is a world view that is characterized by the denial of sacred attributes in nature, a characteristic that has its roots in Greek philosophy, and became firmly established about 2000 years with the Judaeo-Christian-Islamic religious traditions (White 1967).

For much of human history, people have lived in small-scale, kin-based societies; attempting to obtain a subsistence from their immediate surroundings. All of humanity lived in such societies of hunter-gatherers or horticulturalists until the beginning of irrigated agriculture 6000 years ago. Much of the Earth's surface was still covered by them until the European expansion beginning five centuries ago. (Crosby 1986; Cavalli-Sforza *et al.* 1994). It is only now that such societies are finally disappearing (Lee and DeVore 1968; Diamond 1992). The world view of such societies tends to be strikingly different from the modern world view. In particular, the values assigned by such societies to biodiversity are grounded on very different premises.

The stylized facts are as follows. In such societies a relatively small number of people, many of them related to each other, tend to be in face-to-face contact over long periods, often their whole lifetimes. Their relationships to each other are moulded by ties of altruism and reciprocal help (Trivers 1971; Wilson 1978). With hunting, gathering, fishing and low-input agriculture and animal husbandry as the mainstay of subsistence, the people are also closely tied to the natural resources of their immediate environments. They therefore tend to view themselves as members of a community that not only includes other humans, but also plants and animals as well as rocks, springs and pools. People are then members of a community of beings – living and non-living. Their relationships with other community members, be they trees, birds or mountain peaks are moulded by the relationships with other human members of the communities, as recipients of altruistic or mutualistic favours. Thus rivers may be viewed as mothers; the Ganges of India is Gangamai, mother Ganga to inhabitants of the Gangetic plains, and has probably been viewed so for millennia. Animals may be treated as kin; thus antelopes are brothers to the followers of the Bishnoi sect of Rajasthan and Haryana in northwestern India (Sankhala and Jackson 1985). The Koyukan people of Alaska believe that the key to the success of a good bear hunter lies in the respect he shows towards his victims (Nelson 1993).

The manifold restrictions and taboos on the way nature is to be treated (grass burnt, honey collected or deer hunted) are an expression of respect for other non-human members of the community of beings.

Anthropologists have documented such practices; that they are a significant component of the ways in which hunter-gatherer-subsistence cultivator-pastoral people relate to their environment is widely acknowledged (McNeely and Pitt 1985). What is disputed is whether such respect, such restraints, are best viewed as irrational, superstitious practices with no significant implications for conservation of biodiversity, or whether they are to be viewed as practices evolved by societies through a long-term process of trial and error actively to promote sustainable use of biological resources and conservation of biodiversity. In favour of the first view is the mounting evidence of many extinctions of larger birds and mammals by hunter-gatherer-horticulturalist colonists of the Americas, Madagascar, New Guinea, New Zealand and the Polynesian islands (Diamond 1994). But, such extinctions by new colonizers may also be reflections of a long period of striking roots in a locality and of gradual accumulation of experience of how nature responds to human use that must elapse before societies can culturally evolve effective traditions of restraints on resource use (Gadgil and Guha 1992; Gadgil, Berkes and Folke 1993; Gadgil 1995). Thus the early settlers of Madagascar were probably responsible for extinction of some of the largest species of lemurs, but the remaining species then came to be treated as sacred animals, protected against hunting, and so survived to the modern times when the influence of Christianity led to the gradual loss of traditional protection (Jolly 1980) (see Section 11.1.2 for further discussion). Indeed, on balance it appears reasonable to conclude that the many restraints on the use of natural resources that include protection everywhere to keystone resource species such as fig trees protection to highly susceptible stages such as birds breeding communally at a heronry, and protection to entire biological communities of sacred sites such as sacred groves or ponds, may have evolved culturally in response to the need to ensure more sustainable use of biological populations and conservation of biological diversity (Gadgil and Berkes 1991) (also see Sections 11.1, 11.2 and 13.6 for further discussion).

Nelson (1993) and Diamond (1993) have observed that such restrictions on the use of natural resources are often against the short-term interests of individuals – as are environmental regulations in modern societies. There exists, therefore, a private incentive to flout such social conventions, to violate the taboos, and this cannot be contained solely by respect for non-human fellow members of a community of beings. Compliance in such societies is typically assured through two devices: fear of the wrath of offended nature spirits and social sanctions against offenders. Thus traditionally Gangtes, a group of shifting cultivators in the state of Manipur in northeastern India, feared that violation of taboos against cutting of sacred groves may lead to illness or death, even if no other

humans detect the violation. If, however, other group members detected the violation, the offender had to sacrifice a pig to placate the nature spirit; the pig was then shared in a feast with all group members (Hemam and Gadgil, pers. obs.).

Unlike the modern world view people living in such communities do not see the world, living or non-living, natural or artificial, as a warehouse of commodities. They do not see themselves as free to so deploy resources at their disposal as to maximize the satisfaction obtained from enjoyment of such commodities. Rather they value plants, animals, other natural elements as deserving of respect by people, and are afraid of adverse consequences if they violate culturally prescribed norms as to how these non-human elements are to be treated.

This approach came to be rejected as large-scale societies developed following intensification of agriculture and the emergence in society of groups no longer dependent on the natural resources of any particular locality. Such groups have little motivation to ensure sustainable use of the biological resources of any given locality, since they have the option of drawing on the resources of other localities, or of substituting less for more scarce resources (Gadgil and Guha 1992).

Large-scale societies dominated by such groups slowly came to embrace a new world view, and a new value system. This perspective, especially as elaborated in the Judaeo-Christian tradition, set humans not as part of a wider community of beings, but apart. It came to view nature as totally dedicated to the fulfilment of human wants, at the pleasure of people (White 1967). Eastern cultures with religious traditions such as Buddhism, Jainism and Hinduism did not depart as drastically from the perspective of humans as members of a community of beings including other living and non-living elements. So Hindus continue to protect primates, permitting the survival of tens of thousands of *Macaca radiata*, *Macaca mulatta* and *Presbytis entellus* in the thickly settled countryside of India. This countryside is also dotted by hundreds of thousands of *Ficus religiosa* trees. Buddhist shrines in southeast Asia have temple groves attached to them, as do Shinto shrines in Japan. This does not at all mean, however, that these Asian societies have not permitted large-scale erosion of their biological diversity, whether in India or Thailand (Lohmann 1991; Gadgil and Guha 1992).

Societies dominated by Islam, and especially by Christianity, have gone farthest in setting humans apart from nature and in embracing a value system that has converted the world into a warehouse of commodities for human enjoyment. In the process, not only has nature lost its sacred qualities, but most animal species that have a positive symbolic value in other human cultures have acquired very negative connotations in the European culture (Lawrence 1993). Conversion to Christianity has

meant an abandonment of an affinity with the natural world for many forest dwellers, peasants, fishers all over the world (Caulfield 1984). The northeastern hill states of India bordering China and Myanmar supported small scale, largely autonomous shifting cultivator societies until the 1950s. These people followed their own religious traditions which included setting apart between 10 and 30% of the landscape as sacred groves and ponds. Most of these people were drawn into the larger market economy and converted to Christianity by the late 1950s. On so converting to a religious belief system that rejects assignment of sacred qualities to elements of nature, they began to cut down the sacred groves, to bring the land under cultivation, as well as to market rattan and timber. However, they gradually discovered that this led to serious difficulties, especially as the fires set during the slash-and-burn cycle now often spread to their settlements, burning down houses. Many of these people have therefore re-established the sacred groves, although now they are termed safety forests instead (Malhotra 1990; Hemam and Gadgil, pers. obs.). The system of social sanctions against violation of these newly instituted safety forests is, however, identical to that which supported the protection of sacred groves in pre-Christian times. There are many other examples of spontaneous reassertion of protection to forest tracts by local tribal and peasant communities in other parts of India as well.

The establishment of protected areas is the modern equivalent of this. In modern societies, as in traditional ones, protected areas serve the longer-term interests of the members of society. The difference between them lies in the way in which nature is regarded, and in the trade-offs that are regarded as permissible. That is, the difference lies in the beliefs and traditions that determine how nature is regarded in each. Some, however, would argue that these differences may not be fundamental. Indeed Wilson (1984, 1993) believes that humans have an inherent inclination to affiliate with life and life-like processes and that these innate tendencies may be a basis for an appropriate ethic of care and conservation of nature, especially the diversity of life.

12.2.4 Use value: species versus habitats

In all societies, the most visible economic value of biological resources arises from the use of domesticated and wild resources in production and consumption. Such direct uses of biological resources comprise both consumptive uses, e.g. through agriculture, hunting, fishing, grazing or harvesting, etc., and non-consumptive uses, e.g. through recreation, tourism or research and education. Thus, as the names imply, consumptive uses usually entail the exploitation and harvesting of domesticated and wild resources in the production and consumption of economic 'goods', whereas non-consumptive uses can be classified as economic 'services' provided by these resources.

Domesticated biological resources are also an important source of direct use value in many production and consumption activities, including agriculture, mariculture, plantation forestry and tree crops, livestock rearing and pharmaceuticals. In most of these uses, the initial 'genetic material' may originally have been derived from wild resources; however, thanks to modern breeding methods, biochemistry, research and development efforts, the potential uses of 'domesticated' biological resources and material are multiplied and the productivity gains vastly increased. Later chapters in this section report estimates of a range of direct-use values of domesticated biological resources.

However, this is not to say that the 'pool' of domesticated biological resources and genetic material is now, or will ever be, completely independent of the stock of wild resources. There is mounting concern that *ex situ* conservation – the use of zoos, botanic gardens, breeding programmes, germplasm 'laboratories', gene or seed banks and other methods of maintaining species and genetic stocks away from their natural habitats – is not sufficient for sustaining all the domesticated biological resources that we require. For example, Weissinger (1990) stresses the importance of *ex situ* conservation through germplasm technologies in maintaining genetic diversity, but he also acknowledges that such methods cannot conserve the whole range of an organism's diversity; rather they preserve a sample of it. Moreover, this sample is necessarily incomplete. It represents only a portion of the population at the moment of its extraction. This implies that we may not know all the 'useful' properties of wild resources and that we may need to augment continually our existing stock of domesticated resources, genetic material and varieties through appropriating more biological 'raw material' from organisms and their habitats.

Some components of the direct value of such species have already been indicated, including their potential to sustain and improve agriculture; to provide opportunities for medical discoveries and industrial innovations; and to preserve choices for addressing as yet unforeseen problems and opportunities for future generations. Genes transferred to domestic crop plants from their wild relatives can increase yields, improve quality, provide resistance to pests and diseases, extend growing ranges, permit wide hybridization between crop species or between them and related wild species and so on. The major reserve of genetic diversity necessary for the development (and biological protection) of future agricultural plantation and forest crops for the humid tropics resides in the natural forests.

The case for focusing on habitats rather than species is very strong, even if one is interested only in the genetic pool. Indeed, the conservation of biological diversity in the tropics is largely a matter of conserving entire habitats rather than individual species of flora and fauna (Whitmore 1990; Terborgh 1992). First, given the multiplicity and

diversity of species in habitats such as tropical forests and coral reefs there are economies of scale in protecting several species concurrently: the opportunity cost of protecting additional species once one is protected are very low or zero if their habitat is co-terminous. While some species may be more vulnerable than others and require extra protection, by and large, the (marginal) costs of protecting additional species fall precipitously once a habitat is protected for the preservation of one species. Conservation of biological diversity is a public good not only from the standpoint of the beneficiaries but also from the standpoint of the species themselves! (You cannot protect one without protecting others which share the same habitat). The importance of recognizing this fact is that the additional benefits accrued from the conservation of all or most of the species in a habitat may justify the conservation of larger areas, which increases the probability of survival under unfavourable natural conditions, such as changes in temperature and rainfall, and anthropogenic impacts such as air pollution, acid rain and encroachment.

A second reason why conserving habitats is preferable to conserving species is that we are not certain which species are likely to turn out to be the most valuable or for that matter valuable at all. Habitat conservation has an information or quasi-option value in that it keeps our options open until more information becomes available.

A third reason is the complexity of interactions and mutual interdependence among species in tropical habitats, together with our limited understanding of these interactions. This makes it necessary to protect many species to ensure the protection of one. Thus, even if we are not interested in certain species directly as an end in themselves, we may still have to protect them as a means to protecting the species we are interested in. Since these other species are themselves dependent on yet other species for survival, soon the need for the protection of the entire habitat becomes inevitable. The conservation of biological diversity is a joint production function with many protected species as its joint inputs and outputs. The larger the number of species protected, the higher is the probability of survival of the particular species we want to protect. At the limit, full protection of the entire habitat maximizes the probability of survival, assuming that we know enough to delineate the habitat area and that no shifts in habitat take place due to climate changes such as global warming. The interaction of ecological and economic factors would determine the cut-off point between 'critical' and 'non-critical' habitats.

A fourth reason is the relatively narrow range of habitats of several tropical species and the irreversibility of destruction of tropical habitats. Severe modification of a limited number of fragile habitats is likely to result in massive extinction of species since both the capacities of the species to adapt to a new environment and of habitats to

recover their original ecosystem are severely limited. This contrasts with many temperate species which tend to have wide ranges of latitude, temperature and moisture regimes and to exist in habitats that tend to be less fragile than tropical habitats and easier to rehabilitate or 'recreate'. The implication is that for tropical biodiversity conservation a quasi-option value should be imputed to the avoidance of irreversible destruction or severe modification of 'critical' habitats rather than to the (temporary) protection of individual species from extinction. If we knew which species would become valuable and we could protect them *ex situ*, the opportunity costs would have been substantially lower, but we do not have that 'luxury'.
